(Received March 6, 2017)

Doppler Shift Attenuation Method (DSAM) analysis of excited-state lifetimes normally employs thin production targets mounted on a thick stopper foil (“backing”) serving to slow down and stop the recoiling nuclei of interest in a well-defined manner. Use of a thick, homogeneous production target leads to a more complex analysis as it results in a substantial decrease in the energy of the incident projectile which traverses the target with an associated change in the production cross section of the residues as a function of penetration depth. Here, a DSAM lifetime analysis using

* Presented at the Zakopane Conference on Nuclear Physics “Extremes of the Nuclear Landscape”, Zakopane, Poland, August 28–September 4, 2016.

a thick homogeneous target has been verified using the Doppler broadened lineshapes of γ rays following the decay of highly excited states in the semi-magic ($N = 50$) nucleus ^{94}Ru . Lifetimes of excited states in the ^{94}Ru nucleus have been obtained using a modified version of the **LINESHAPE** package from the Doppler broadened lineshapes resulting from the emission of the γ rays, while the residual nuclei were slowing down in the thick (6 mg/cm^2) metallic ^{58}Ni target. The results have been validated by comparison with a previous measurement using a different (RDDS) technique.

DOI:10.5506/APhysPolB.48.325

1. Experimental details

The experiment was performed at the Grand Accélérateur National d'Ions Lourds (GANIL) in France. High-spin states in the semi-magic ($N = 50$) nucleus ^{94}Ru were populated in the $^{40}\text{Ca}(^{58}\text{Ni},4p)^{94}\text{Ru}^*$ fusion-evaporation reaction. The ^{40}Ca ions were accelerated to an energy of 150 MeV, degraded 128 MeV in a thin Ta foil, and used to bombard target foils consisting of 99.9% isotopically enriched ^{58}Ni with the areal density of 6 mg/cm^2 , enough to stop the fusion products. The beam intensity varied between 5–10 pA during 14 days of irradiation time. The γ rays emitted from the reaction were measured using the EXOGAM germanium detector array [1] in its compact configuration comprising 11 large clover detectors. Each clover consists of four germanium crystals and each crystal is segmented in four quadrants of equal volume. Seven clover detectors were placed at 90° and four detectors at 135° with respect to the beam axis. The Ge detectors were surrounded by escape suppression shields consisting of BGO (bismuth germanate) scintillators to improve the spectrum quality. The fusion products corresponding to different reactions were selected using the DIAMANT CsI(Tl) charged-particle detector system [2, 3] which consisted of 80 CsI scintillators, and the Neutron Wall liquid scintillator detector array [4], consisting an array of 50 organic liquid scintillator detectors covering a 1π solid angle in the forward direction. The trigger condition was fulfilled if one or more γ rays was registered in the Ge detectors together with at least one neutron in the Neutron Wall. The latter signal was determined by a hardware threshold on the zero-crossing time of the neutron detector signals after passing through a shaping amplifier. The neutron hardware trigger was sufficiently relaxed to allow for a significant fraction of events which were not associated with neutron emission to be collected. In the off-line analysis, when needed, neutrons were selected cleanly by setting two-dimensional gates on the neutron time-of-flight *versus* the zero-crossover time. The energy calibration was performed using standard radioactive sources (^{60}Co , ^{152}Eu).

2. Data analysis and results

The off-line analysis of selected γ -ray coincidence matrices and spectra was performed using the RADWARE software package [5]. The observation of Doppler broadened lineshapes also enabled the determination of level lifetimes using the Doppler Shift Attenuation Method (DSAM) [6]. In the standard DSAM measurements, a thin target coupled with a thick backing material ensures that the production cross section for the fusion-evaporation residues can be assumed to be constant across the target. Using a thick homogeneous production target results in a substantial decrease in the energy of the incident projectile as it traverses the target with an associated change in the production cross section of the residues as a function of penetration depth. Furthermore, only a certain fraction of the full target thickness will contribute significantly to the residue production in a given reaction channel, while the rest of the target thickness acts merely as the stopping medium, *i.e.* corresponds to the backing in a conventional measurement. The knowledge of the residue production rate as a function of target depth and the associated effective target thickness follows from the information on the production cross-section dependence on the beam energy and the evolution of the latter along the target thickness. The cross section for the production of the fusion residues as a function of beam energy can be obtained from experimental data and/or from statistical model calculations using, *e.g.*, the PACE4 code [7]. Here, due to the strong variation of the fusion cross section close to the Coulomb barrier, the DSAM analysis is particularly challenging and we rely on experimental cross section data obtained by Bourgin *et al.* [8]. The stopping powers used in the analysis were calculated using the SRIM software package [9].

Lifetimes of excited states in the ^{94}Ru nucleus have been obtained from an analysis of the Doppler broadened lineshapes resulting from the emission of the γ rays, while the residual nuclei were slowing down in the thick (6 mg/cm^2) metallic ^{58}Ni target. The program LINESHAPE [10] in a modified version, see Ref. [11], was used to calculate the expected Doppler shape for a given γ -ray transition at a particular detector angle and perform least-square fits to the corresponding experimental spectrum in order to extract the level lifetime (τ). In this work, the method is verified using the $I^\pi = 18^+$ state in the ^{94}Ru nucleus. The gamma-ray spectra have been generated with the gate on a transition below in the level scheme using (GTB) procedure [6]. The example of results of the fit of transitions lineshapes are shown in Fig. 1.

The results are given in Table I. The spin-parity assignments and transition energies proposed by Ghazi Moradi *et al.* [12] are adapted here. The data were sorted in $(E_\gamma - E_\gamma)$ matrices according to detector angle. The observed γ rays of interest were analyzed for different angles simultaneously for the determination of the lifetimes.

Fig. 1. Representative output fits of the Doppler shapes for the 486 keV transition from the ^{94}Ru nucleus, obtained using the LINESHAPE package [11].

TABLE I

Lifetime value of the 18^+ level in the ^{94}Ru nucleus from the present work in comparison with the previously reported result, which employed the Recoil Distance Doppler Shift Method (RDDS).

E_γ [keV]	$I_i \rightarrow I_f$	$\tau(\text{ps})$ present work	$\tau(\text{ps})$ literature [13]
486	$18^+ \rightarrow 17^+$	0.54(5)	0.52(3)

3. Conclusions

The lifetime of the 18^+ excited state in the ^{94}Ru nucleus has been measured and used to benchmark the applicability of the DSAM technique for a fusion-evaporation reaction at the Coulomb barrier with a thick homogeneous production target. The results agree with the lifetime measured previously using the RDDS technique, hence confirming the validity of the approach. In addition, lifetime values have been measured for the first time for the $19^+ \rightarrow 18^+$, $17^+ \rightarrow 16^+$ and $15^+ \rightarrow 14^+$ M1 transitions in the yrast cascade. These results will be reported elsewhere [14].
