Hippocampal θ (3–12 Hz) oscillations are implicated in learning and memory, but their functional role remains unclear. We studied the effect of the phase of local θ oscillation on hippocampal responses to a neutral conditioned stimulus (CS) and subsequent learning of classical trace eyeblink conditioning in adult rabbits. High-amplitude, regular hippocampal θ-band responses (that predict good learning) were elicited by the CS when it was timed to commence at the fissure θ trough (Trough group). Regardless, learning in this group was not enhanced compared with a yoked control group, possibly due to a ceiling effect. However, when the CS was consistently presented to the peak of θ (Peak group), hippocampal θ-band responding was less organized and learning was retarded. In well-trained animals, the hippocampal θ phase at CS onset no longer affected performance of the learned response, suggesting a time-limited role for hippocampal processing in learning. To our knowledge, this is the first study to demonstrate that timing a peripheral stimulus to a specific phase of the hippocampal θ cycle produces robust effects on the synchronization of neural responses and affects learning at the behavioral level. Our results support the notion that the phase of spontaneous hippocampal θ oscillation is a means of regulating the processing of information in the brain to a behaviorally relevant degree.

studied whether the phase of the \( \theta \) oscillation at stimulus onset might have effects on learning about that stimulus. To this end, the rabbits were trained for 10 sessions in trace eyeblink classical conditioning, with the conditioned stimulus (CS, the same tone as before) timed to start at either the peak and trough of the \( \theta \) oscillation (peak and trough). For animals in the Trough group \((n = 5)\), treatment was identical to that in the Peak group, except during the first 10 conditioning sessions, trials were presented contingent on the trough of the \( \theta \) oscillation (trough). The yoked control group (YC, \( n = 6 \)) was trained irrespective of their neural state (random) at all times. (B) Representative example of the approximate placement of a linear probe (dashed line) used in recording hippocampal LFPs. Exact locations of single electrodes used for detecting \( \theta \) in three animals are marked with filled circles. (C) Examples of hippocampal fissure LFPs prior to and during the presentation of the tone (conditioned stimulus) and the air puff (unconditioned stimulus). The top and middle panels depict single-trial LFPs in representative animals in the Peak (top) and Trough (middle) groups recorded during the first session of conditioning (beginning of “Trace EBCC 10 sessions” shown in 1A). The bottom panel in C represents LFP from the same animal as in the top panel (peak) from session 11 (beginning of “Trace EBCC 6 sessions” in A). Note that now the conditioned stimulus was triggered by the absence of \( \theta \) (T –). In C, the raw LFPs are printed in black and the \( \theta \)-band \((4–8\, \text{Hz})\) filtered signal in gray. Arrowheads indicate the onset of the 200-msec tone used as a conditioned stimulus and the onset of the 100-msec air puff toward the eye used as an unconditioned stimulus.

### Results

**Hippocampal \( \theta \) activity was recorded from near the fissure**

In all animals, recording electrodes (32-channel linear probes or single wire electrodes) were inserted into the dorsal hippocampus (Fig. 1B). The data from animals implanted with single electrodes were combined with the data from the animals implanted with linear probes, as, to time the presentation of stimuli, the oscillatory state in the hippocampal fissure was monitored for each animal by the signal from only one electrode or probe recording site. The source of the signal was determined online based on the known phase reversal of hippocampal \( \theta \) between the CA1 and the dentate gyrus, the variation in \( \theta \) amplitude along the hippocampal cell layers, and the occurrence of ripples (Chrobak and Buzsáki 1996) in the CA1 region and in the CA3 region. The recording site/electrode with maximal \( \theta \) amplitude in a given animal was selected to trigger trials based on the phase of \( \theta \) oscillation (see Fig. 1C). The signal from the same single recording site/electrode per animal was also used in analyzing hippocampal responses to the CS.

The results of off-line analyses of the \( \theta \) amplitude and phase variation from a representative animal implanted with a 32-channel linear probe are depicted in Figure 2, panels C,D. As in rats [see for example (Bragin et al. 1995)], \( \theta \) is highest in amplitude near the hippocampal fissure and its phase reverses between the CA1 pyramidal layer and the fissure/dentate gyrus. Curiously, in rabbits, the phase of \( \theta \) oscillation remains constant across the fissure, the dentate gyrus and the hilus. Note that in rats, comparison of the dentate gyrus and the hilus also shows a phase-shift in \( \theta \) (Buzsáki et al. 1983).

**Hippocampal \( \theta \)-band responses to a neutral tone were modulated by ongoing, spontaneous \( \theta \) oscillations**

During a single session conducted prior to any conditioning, all the rabbits were presented with a 200-msec, 80-dB, 4-KHz tone. For the animals later assigned to the experimental groups, the tone was presented 300 times either during periods of spontaneously occurring hippocampal \( \theta \) activity \((T+, n = 5)\) or irrespective of neural state \((T-, n = 6)\). For the animals assigned to the YC group \((n = 6)\) for reasons of technical difficulties in obtaining neural recordings, stimuli were presented irrespective of neural state. This session was carried out to find out if \( \theta \) phase, and the neural state at large \((T+\) versus random\)), affects \( \theta \)-band hippocampal responses to a neutral peripheral stimulus. By \( \theta \)-band responses we refer to responses occurring at the frequency band of 4–8 Hz. Phase-locking and relative amplitude, quantified as the \( \theta \) ratio \((\%)) for these responses, is analyzed separately. For details on these measures, please see Materials and Methods.

**First we analyzed the effects of the preceding neural state (T+ versus random) on the relative amplitude and phase-locking of the hippocampal fissure \( \theta \)-band responses to the neutral tone**
The ongoing $\theta$ oscillation at tone onset. However, as hypothesized, better phase-locked responses were elicited when the tone onset fell at the trough of the $\theta$ cycle ($0.53 \pm 0.05$) compared with the peak of the $\theta$ cycle ($0.29 \pm 0.05$). This effect was evident in four out of the five animals. Figure 2 depicts examples of event-related averages and current source density plots (please see Materials and Methods) of local-field potentials (LFPs) recorded from the hippocampus with a linear probe in response to the tone alone when it commenced at the peak (A) or the trough (B) of the $\theta$ cycle in one representative animal. Visual comparison of A and B suggests better phase-locking of $\theta$-band responses to the tone when it was presented to $\theta$ trough compared with $\theta$ peak. Although the effect was not quite statistically significant at a group level ($t_{(4)} = 2.62, P = 0.059$), we carried on with the experiment as planned.

Figure 2. $\theta$ Phase modulates hippocampal responses to peripheral stimulation. In naïve animals, the conditioned stimulus (200-msec tone) alone elicited bigger and better phase-locked hippocampal $\theta$-band responses when presented to the trough (B) of the hippocampal fissure $\theta$ cycle than when presented to the peak (A) of the cycle. The amplitude (C) of the $\theta$ oscillation was maximal near the hippocampal fissure. The phase (D) of $\theta$ oscillation reversed between the CA1 and the fissure and remained oscillation reversed between the CA1 and the fissure and remained reversed between the CA1 and the fissure and remained reversed between the CA1 and the fissure and remained.

Baseline responses to the tone, spontaneous $\theta$ ratios and intertrial intervals did not differ between groups

The 11 animals with functional recording electrodes were assigned to two experimental groups (Peak, $n = 6$ versus Trough, $n = 5$) for subsequent trace eyeblink conditioning. Half the animals in the Peak and Trough groups had, prior to conditioning, received tone-alone presentations to a random brain state and half during $\theta$. There was no statistically significant difference between the Peak and Trough groups in phase-locking ($0.19 \pm 0.04$ versus $0.28 \pm 0.05$) or relative amplitude ($0.75 \pm 0.4$ percentage units versus $83\% \pm 5$ percentage units, respectively) of the hippocampal fissure $\theta$-band responses to the tone presented alone prior to conditioning ($F_{(1,9)} = 0.001$). Mean ITI was 50.4 ± 0.04 sec during the first conditioning session.
session and 57.6 ± 1.7 sec during the tenth conditioning session. This change was not part of the experimental design but it was expected in light of our previous observations indicating non-θ (T−) periods occur more often as conditioning proceeds (Nokia and Wikgren 2014). In other words, periods of prominent spontaneous θ activity become less frequent across conditioning as the animal presumably becomes less attentive toward the, now familiar, situation. Further analyses indicated that no changes across training blocks or differences between groups in ITIs occurred during the six sessions (three blocks) of T− conditioning (rm ANOVA: main effect of block: F(2,260) = 2.11, P = 0.142, interaction of block and group: F(4,260) = 0.16, P = 0.955 and main effect of group: F(2,123) = 0.52, P = 0.607). The average ITI during this latter training phase was 53.2 ± 2.6 sec.

All in all, these analyses indicate no differences in baseline responding to the tone before it was used as the CS and no differences in either the level of spontaneous hippocampal θ activity or ITIs between the groups. This implies that any differences or changes across conditioning in hippocampal responding to the tone-CS or learning can be interpreted to be a result of our experimental manipulations. Note that as the tone elicited larger θ-band responses in animals in which it was presented contingent on θ (T+ versus random), this tone-alone treatment type was included as a covariate in the repeated-measures ANOVAs when examining differences between the experimental groups and changes across conditioning.

Fissure θ trough-contingent conditioning enhanced hippocampal θ-band responses to the CS while peak-contingent training impaired learning

Our main aim in this experiment was to study whether the phase of θ oscillation at stimulus onset might have effects on learning about that stimulus. To this end, rabbits were trained for 10 sessions in trace eyeblink classical conditioning (see Materials and Methods), with the tone-CS timed to start either at the peak (Peak group) or the trough (Trough group) of the θ cycle. The YC animals were trained simultaneously and received trials irrespective of their neural state. The phase-locking and relative amplitude of the hippocampal fissure θ-band responses to the CS as a function of the trace eyeblink conditioning are presented in Figure 3A–D.

Our hypothesis was that the hippocampal responses would be better phase-locked to the onset of the CS and possibly also higher in amplitude in the Trough group than in the Peak group. Both expectations were realized. First, phase-locking of hippocampal θ-band responses to the CS was greater in the Trough group compared with the Peak group (rm ANOVA, main effect of block: F(4,32) = 0.93, P = 0.457; interaction of block and tone-alone treatment type: F(4,32) = 0.93, P = 0.460; interaction of block and group: F(4,32) = 4.31, P = 0.007, η²(ε) = 0.35; main effect of tone-alone treatment type: F(1,8) = 0.42, P = 0.536; main effect of group: F(1,8) = 110.35, P < 0.001, η²(ε) = 0.93) (see Fig. 3A, left-most panel). Phase-locking remained stable across conditioning in both groups (Peak: F(4,16) = 2.33, P = 0.091; Trough: F(4,16) = 2.84, P = 0.059). Second, the relative amplitude of the hippocampal θ-band responses to the CS was greater in the Trough group compared with the Peak group (main effect of group: F(1,8) = 11.46, P = 0.010, η²(ε) = 0.59) (see Fig. 3C, left-most panel). In addition, the relative amplitude of the responses decreased as a
function of conditioning in both groups (main effect of block: $F_{(4,32)} = 6.85$, $P < 0.001$, $\eta^2_p = 0.46$; interaction of block and group: $F_{(4,32)} = 1.96$, $P = 0.124$; interaction of tone-alone treatment type and block: $F_{(4,32)} = 1.32$, $P = 0.285$; main effect of tone-alone treatment type: $F_{(1,8)} = 0.03$, $P = 0.873$).

Intrigued by the high level of phase-locking in the Trough group we also ran some analyses comparing our current data to results obtained in our previously published studies: In fact, the hippocampal responses elicited in the Trough group were more regular than those we have previously observed (Nokia and Wikgren 2014), either when the CS was presented contingent on hippocampal $\theta$ $[T-\theta$, independent samples $t$-test on phase-locking of $\theta$-band responses to the CS elicited during the first conditioning block: $t_{(14)} = 9.93$, $P < 0.001$], contingent on the absence of $\theta$ $[T-\theta$, independent samples $t$-test on phase-locking of $\theta$-band responses to the CS elicited during the first conditioning block: $t_{(14)} = 5.21$, $P < 0.001$] or irrespective of ongoing neural state [random, $t_{(11)} = 7.85$, $P < 0.001$]. In contrast, the responses to the tone-CS presented at the $\theta$ peak were markedly less phase-locked and smaller in amplitude, and did not differ from those elicited in any of the groups in our earlier study [see Nokia and Wikgren (2014)].

In sum, as when presented alone, the tone presented as a CS during trace eyelink conditioning elicited better phase-locked hippocampal $\theta$-band responses when it was timed to start at the trough of the spontaneously occurring $\theta$ oscillation than when it was timed to start at the $\theta$ peak (irrespective of ongoing neural state, in the absence of $\theta$ or randomly during $\theta$). This effect was consistent across conditioning. In addition, the CS also elicited larger amplitude hippocampal $\theta$-band responses when it was presented to the trough compared with when it was presented at the peak. The amplitude of the $\theta$-band responses decreased across conditioning. This attenuation took place irrespective of the timing of the CS in relation to $\theta$ phase.

These results above suggest that $\theta$ phase-contingent conditioning might also affect learning at the behavioral level. Our hypothesis was that animals trained at the trough of hippocampal fissure $\theta$ oscillation would acquire trace eyelink conditioning at the behavioral level faster/better than animals trained at the peak of oscillation or irrespective of their neural state. The behavioral results of the experiment are depicted in Figure 4A-C. Learned responding increased across the first five blocks of conditioning in all groups ($\eta^2_p$ ANOVA, main effect of block: $F_{(4,52)} = 19.00$, $P < 0.001$, $\eta^2_p = 0.59$; interactions of block and tone-alone treatment type and block and group: $F_{(4,52)} = 2.20$, $P = 0.132$ and $F_{(4,52)} = 0.98$, $P = 0.436$, respectively; main effect of tone-alone treatment type: $F_{(1,13)} = 1.68$, $P = 0.218$) (see Figure 4A, left-most panel). However, the animals in the Peak group elicited significantly fewer conditioned responses (CRs) across the conditioning sessions compared with those in the YC and Trough groups (main effect of group: $F_{(2,13)} = 5.33$, $P = 0.020$, $\eta^2_p = 0.45$; pairwise Bonferroni-corrected comparisons: Peak versus Trough: $P = 0.053$, Peak versus YC: $P = 0.063$, Trough versus YC: $P = 1.000$). Analysis of the cumulative percentage of CRs at the end of the first 10 sessions of conditioning confirmed this observation (one-way ANOVA: $F_{(2,14)} = 6.08$, $P = 0.013$; Bonferroni-corrected pairwise comparisons: Peak versus Trough: $P = 0.096$, Peak versus YC: $P = 0.014$, Trough versus YC: $P = 1.000$) (Fig. 4B). The animals in the YC group made a conditioned response (CR) in 31% ($\pm 0.03$ percentage units) of the trials, compared with 78% ($\pm 0.02$) in the Trough and only 16% ($\pm 0.04$) in the Peak group. Of the YC animals five out of six (83%) reached the learning criterion of 60% CRs within the first 10 sessions of $\theta$-contingent conditioning. In contrast, in the Peak group only 1 out of 6 (17%) and in the Trough group only two out of five (40%) animals reached criterion within the first 10 conditioning sessions. According to the binomial test, learning was significantly retarded in both the Peak and the Trough groups compared with YC: Peak: $P = 0.001$; Trough: $P = 0.035$. The YC animals performed the fifth CR after an average of 72 ± 9 paired trials whereas those in the Peak group required 107 ± 31 trials and those in the Trough group 48 ± 19 trials to accomplish the same ($F_{(2,14)} = 1.83$, $P = 0.197$).

To conclude, the acquisition of a behavioral learned response was retarded by $\theta$-contingent conditioning, when the CS was timed to start at the peak of the $\theta$ cycle. Despite enhancing hippocampal $\theta$-band responding to the CS, presenting conditioning trials to the trough of fissure $\theta$ had little effect on the acquisition of a behavioral CR.
Continued conditioning in the absence of \( T^- \) led to attenuated and less phase-locked hippocampal \( \theta \)-band responses while learned responding was further increased.

To maximize the number of animals that learned, we trained all the rabbits for another six sessions. Now, the animals previously trained contingent on \( \theta \) phase (Peak and Trough groups) were trained in the explicit absence of \( \theta \) (\( T^- \)) to maximize the number of animals that learned (Nokia and Wikgren 2014). The animals in the YC group continued to be trained irrespective of their neural state. In one animal initially assigned to the Peak group, the recording electrode broke during the night between sessions 13 and 14 and hence the animal was excluded from further training and analyses.

Our hypothesis was that \( T^- \) conditioning would not change the hippocampal \( \theta \)-band responses to the CS considerably. If anything, we expected to see a decrease in phase-locking in the animals previously trained at the trough of \( \theta \). First, possible changes in the \( \theta \)-band response amplitudes and phase-locking as a result of switching from \( \theta \) phase-contingent to \( T^- \) conditioning was studied in both groups (Peak and Trough) separately. Note that in Figure 3, data are presented compressed into blocks of two sessions; for this analysis, however, a paired-samples \( t \)-test was conducted on measures obtained during the last \( \theta \) phase-contingent session (session 10) and the first \( T^- \) session (session 11). In the Peak group, the phase-locking of the hippocampal fissure \( \theta \)-band responses to the CS remained the same, even when it was timed to start in the absence of \( \theta \) (\( t_{\theta,1} = 0.14, P = 0.897 \)), and the relative amplitude of the response decreased significantly (\( t_{\theta,1} = 7.01, P = 0.001 \)) (see Figs. 3A,C, respectively). In the Trough group, both the phase-locking as well as amplitude of the hippocampal \( \theta \)-band responses decreased significantly when the conditioning protocol was switched from \( \theta \) trough-contingent to \( T^- \) (\( t_{\theta,1} = 7.36, P = 0.002 \) and \( t_{\theta,1} = 13.51, P < 0.001 \), respectively). To summarize, switching from \( \theta \) phase-contingent to \( T^- \) conditioning attenuated hippocampal \( \theta \)-band responses to the CS. In addition, only in animals previously conditioned at \( \theta \) trough, also the phase-locking of the responses to the CS decreased when training was switched to \( T^- \).

Next, we studied whether hippocampal \( \theta \)-band responses changed across the \( T^- \) conditioning (three blocks of two sessions) and whether the differences between groups in hippocampal responding (Peak versus Trough) were still evident even though conditioning was now carried out in an identical way, that is, in the explicit absence of \( \theta \). The CS continued to elicit better phase-locked responses in the animals previously trained at \( \theta \) trough compared with those previously trained at \( \theta \) peak also during the \( T^- \) conditioning (rm ANOVA, main effect of group: \( F_{1,7} = 15.35, P = 0.006, \eta_p^2 = 0.69 \); main effect of block: \( F_{2,14} = 0.12, P = 0.884 \); interaction of block and tone-alone treatment type: \( F_{2,14} = 1.67, P = 0.223 \); interaction of block and group: \( F_{2,14} = 0.74, P = 0.494 \); main effect of tone-alone treatment: \( F_{1,7} = 2.64, P = 0.148 \) (see Fig. 3A middle panel, gray background)). However, there were no significant differences between groups or changes across the \( T^- \) conditioning in the relative amplitude of the \( \theta \)-band responses to the CS (rm ANOVA, main effect of group: \( F_{1,7} = 4.30, P = 0.077 \); main effect of block: \( F_{2,14} = 1.69, P = 0.220 \); interaction of block and tone-alone treatment type: \( F_{2,14} = 0.22, P = 0.805 \); interaction of block and group: \( F_{2,14} = 2.59, P = 0.110 \); main effect of tone-alone treatment: \( F_{1,7} = 0.474 \) (see Fig. 3C middle panel, gray background)). To summarize, during \( T^- \) conditioning, phase-locking of hippocampal \( \theta \)-band responses to the CS diminished yet continued to be higher in animals previously trained at \( \theta \) trough compared with those previously trained at \( \theta \) peak. Hippocampal \( \theta \)-band response amplitude was diminished overall compared with \( \theta \) phase-contingent conditioning and a statistically significant difference between the previous Peak and Trough groups was no longer evident.

In terms of learning trace eyeblink conditioning, we expected animals in the experimental groups (Peak and Trough) to learn the task during the \( T^- \) training, if they had not already done so during the first 10 conditioning sessions conducted contingent on \( \theta \). We used \( T^- \) training because in our previous study (Nokia and Wikgren 2014) it led to a greater proportion of animals learning compared with random presentation of training trials (note that \( T^+ \) conditioning had no such effect). Conditioned responding continued to increase in all groups during the second phase of training (rm ANOVA: main effect of block (3): \( F_{2,24} = 12.71, P = 0.001, \eta_p^2 = 0.51 \); interaction of group (3) and block: \( F_{2,24} = 3.09, P = 0.062 \); interaction of tone-alone treatment type and block: \( F_{2,24} = 0.49, P = 0.544 \); main effect of group: \( F_{2,12} = 0.44, P = 0.655 \); main effect of tone-alone treatment type: \( F_{2,12} = 1.85, P = 0.199 \) (see Fig. 4A middle panel, gray background)). At the end of the \( T^- \) conditioning, the cumulative percentage of CRs was 50% in the YC group compared with 32% in the Peak and 40% in the Trough group (\( F_{2,13} = 2.72, P = 0.103 \)). By the end of 16 d of conditioning, all (100%) of the YC animals, three out of five (60%) animals previously trained at \( \theta \) peak and 4 out of 5 (80%) animals previously trained at \( \theta \) trough reached the learning criterion of 60% CRs during at least one session. The binomial test could not be run because all the animals in the YC group learned. Of the animals that eventually learned, those in the YC group reached the traditional learning criterion of eight CRs in nine consecutive trials after an average of 401 ± 43 trials whereas those first trained at \( \theta \) peak and then in the absence of \( \theta \) required 547 ± 54 trials and those first trained at \( \theta \) trough and then in the absence of \( \theta \) 456 ± 71 trials to perform at the same level (\( F_{2,10} = 1.62, P = 0.246 \). To conclude, after \( T^- \)-conditioning the learning outcome in the Peak and Trough groups was similar to that of the YC group.

High-amplitude, well phase-locked hippocampal fissure \( \theta \)-band responses to the conditioned stimulus early in training predicted better learning of trace eyeblink conditioning

Previous studies indicate a correlation between hippocampal function and learning only, or at least especially, early in training (Nokia et al. 2009). To study the link between hippocampal \( \theta \)-band responses and learning, we calculated correlations between the relative amplitude/phase-locking of hippocampal \( \theta \)-band responses to the CS during the first conditioning session and the percentage of CRs elicited during conditioning (blocks 1–8). For this, animals from both the Peak and the Trough groups were pooled. A high \( \theta \) ratio in response to the CS during the first conditioning session predicted a higher CR percentage during conditioning blocks 3–6 (\( r = 0.656–0.694, P = 0.018–0.028, n = 11 \)). The correlations between the \( \theta \) ratio and conditioned responding during blocks 1–2 and 7–8 were not statistically significant (\( r = 0.332–0.495, P = 0.146–0.318, n = 11/10 \)). In addition, highly phase-locked responding during the very first conditioning session predicted a higher percentage of CRs during conditioning blocks 3 and 4 (\( r = 0.760/0.693, P = 0.007/0.018, n = 11, \) respectively). There was also a close to significant correlation with conditioned responding during block 5 (\( r = 0.553, P = 0.078, n = 11 \)). Correlations with CR percentage during blocks 1, 2, and 6–8 were not significant (\( r = 0.137–0.466, P = 0.149–0.706, n = 11 \)). To summarize, high-amplitude, temporally uniform hippocampal \( \theta \)-band responses to the CS at the start of conditioning anticipated good learning. Hippocampal responding early in training was

Hippocampal \( \theta \) phase and learning
correlated to conditioned responding specifically in the middle of training, when the conditioned response is being acquired and its performance rate starts to rise rapidly (Prokasy 1984).

**θ** phase at CS onset did not affect conditioned responding in well-trained animals

After 16 sessions of conditioning, two more sessions were carried out, now reverting back to the procedure of presenting the trials contingent on hippocampal **θ** phase for animals in the Peak and Trough groups. However, now half the trials were presented to the trough and half to the peak of the **θ** cycle recorded from the hippocampal fissure, in a random order. Animals in the YC group remained to be conditioned irrespective of their neural state. Our hypothesis was that a conditioned response would be more likely to occur in response to a CS presented at **θ** peak compared with when it was presented at **θ** trough. This would have indicated superior memory retrieval at **θ** peak (Hasselmo et al. 2002).

The CS continued to elicit better phase-locked **θ**-band responses from the hippocampal fissure if it was timed to start at the trough of the **θ** cycle compared with the peak of the **θ** cycle (rm ANOVA with group [Peak versus Trough] as a between-subjects factor: main effect of trial type [peak versus trough]: $F_{1,8} = 109.83$, $P = 0.001$, $\eta^2_p = 0.93$). The analysis also revealed a significant interaction of trial type and group ($F_{1,8} = 7.83$, $P = 0.023$, $\eta^2_p = 0.50$) and a main effect of group ($F_{1,8} = 7.43$, $P = 0.026$, $\eta^2_p = 0.48$) (see Fig. 3B). Due to the interaction, groups were further analyzed separately using paired samples t-test. This confirmed that the CS elicited better phase-locked **θ**-band responses in both groups when presented to the trough of **θ** during the test sessions (Peak: $t_{41} = 4.93$, $P = 0.008$; Trough: $t_{49} = 10.58$, $P = 0.001$; see Fig. 3B). However, the CS also still elicited better phase-locked responses in animals initially trained at **θ** trough compared with animals initially trained at **θ** peak, when it was presented to the trough of the **θ** cycle (one-way ANOVA: $F_{1,8} = 12.98$, $P = 0.007$). The phase-locking of responses to the CS was similar in both groups when it was timed to commence at the peak of the fissure **θ** cycle ($F_{1,8} = 0.93$, $P = 0.363$). Also, there were no statistically significant differences between groups (Peak versus Trough group, trials presented at the peak/trough: $F_{1,8} = 3.94/3.75$, $P = 0.038/0.089$) or effects of **θ** phase (trials presented to peak versus trough, Peak group: $t_{41} = 0.06$, $P = 0.578$; trials presented to peak versus trough, Trough group: $t_{41} = 1.95$, $P = 0.123$) on the relative amplitude of the hippocampal fissure **θ**-band responses (see Fig. 3D). However, the relative amplitude of the **θ**-band responses elicited in response to the CS in the hippocampal fissure attenuated in animals initially trained at the peak of **θ** when training was switched back from T to **θ** phase-contingent (last T session versus first test session, paired samples t-test: $t_{41} = 5.44$, $P = 0.006$). The same was not true for the Trough group ($t_{41} = 1.96$, $P = 0.122$). Overall, conditioned responding during the two test sessions remained at the same level compared with the last T-conditioning block (paired samples t-tests: YC: $t_{41} = 0.81$, $P = 0.457$; Peak: $t_{41} = 0.01$, $P = 0.990$; Trough: $t_{41} = 2.09$, $P = 0.105$; see Fig. 4A, right-most panel). Last but most important, behavioral responding did not differ between the peak and trough trials (paired samples t-tests: Peak group: $t_{41} = 0.48$, $P = 0.654$; Trough group: $t_{41} = 0.69$, $P = 0.526$; see Fig. 4C).

To summarize, **θ** phase continued to modulate hippocampal responses to the CS even after extensive training. In addition, animals initially trained at **θ** trough continued to exhibit better phase-locked hippocampal **θ**-band responses to the CS compared with animals initially trained at **θ** peak. This effect was limited to trials during which the CS commenced at **θ** trough. Most important, despite these clear effects on hippocampal responding, **θ** phase had no effect on memory retrieval at the behavioral level.

**Discussion**

Hasselmo and colleagues (Hasselmo et al. 2002; Hasselmo and Stern 2014) have proposed that the function of hippocampal **θ** oscillations in learning and memory is to enable separate time windows for the encoding and retrieval of memories by regulating information flow within the hippocampo-entorhinal loop. Inspired by this idea, we studied whether the phase of hippocampal **θ** oscillation at stimulus onset has an effect on hippocampal responding to that stimulus and whether this affects learning about that stimulus in the context of classical eyelink conditioning in rabbits. Our results indicate that the most regular hippocampal responses occurred to stimuli presented at the trough of fissure **θ**, whereas the responses to stimuli presented at the peak of fissure **θ** were less organized. Overall, high-amplitude, temporally regular hippocampal **θ**-band responses early in training predicted better learning. Presenting the CS at **θ** peak retarded learning whereas the acquisition of a learned response was little affected in the Trough group, despite the enhanced hippocampal **θ**-band responses to the CS. Across continued conditioning and in well-trained animals, the association between hippocampal responses to the CS and behavioral learned responses vanished, suggesting that the role for hippocampal function in learning is time-limited. In sum, **θ** phase predetermines both hippocampal responding to peripheral stimuli and learning about those stimuli indicating that it is involved in regulating processing of information in the brain up to a behaviorally relevant degree.

According to the computational model by Hasselmo and colleagues (Hasselmo et al. 2002; Hasselmo and Stern 2014), the phase of hippocampal **θ** responses in the Trough group resembles the phase-locking or resetting of hippocampal **θ** oscillation determined whether the hippocampus preferentially processes input from the entorhinal cortex, leading to memory encoding, or from the CA3 autoassociative network, leading to memory retrieval. To a certain degree, our results comply with the model: a brief auditory stimulus evoked large and temporally well-organized responses at the **θ**-band within the hippocampus when timed to start specifically at the trough of a **θ** cycle recorded from the hippocampal fissure. In fact, the hippocampal responses elicited were more regular than those we have previously observed (Nokia and Wikgren 2014), either when the CS was presented contingent on hippocampal **θ** or irrespective of ongoing neural state. In contrast, the responses to the tone-CS presented at the **θ** peak were markedly less phase-locked and smaller in amplitude, and did not differ from those elicited in any of the groups in our earlier study (Nokia and Wikgren 2014). The high phase-locking of **θ**-band responses in the Trough group resembles the **θ** res error observed in the dentate gyri of rats performing a working memory task involving both visual and auditory peripheral stimuli (Givens 1996). It has been demonstrated in rats that LTP is preferentially induced if stimulation is timed to occur during the peak of the CA1 **θ** (trough of fissure **θ**) not only when the oscillation occurs spontaneously (Holscher et al. 1997) but also when it is evoked and reset by a peripheral stimulus (McCartney et al. 2004). Thus, phase-locking or resetting of hippocampal **θ** oscillation to the stimulus onset creates windows of opportunity for enhanced processing of subsequent relevant stimuli. Together with these earlier findings our current results imply that hippocampal processing of related peripheral stimuli occurring close in time (within 500 msec to 1 sec of each other) could be brought to or near the maximum by presenting the stimuli consistently at the hippocampal **θ** trough. In further studies, conditioning should be conducted in a manner where both the CS and the unconditioned stimulus are presented consistently to the trough/peak of the hippocampal **θ** oscillation. One would expect superior learning if both stimuli occur at fissure **θ** trough.

Consistent with the theory by Hasselmo et al. (2002), compared with a yoked control group, learning was severely retarded
when the conditioned stimulus was presented at the peak of fissure \( \theta \). Learning was also not improved in the group trained at the fissure \( \theta \) trough. That is, even though the conditioned stimulus evoked unusually regular responding in the hippocampus, and even though high regularity, once again (Nokia and Wikgren 2014), predicted good learning in general, it was not enough to improve the acquisition of the behavioral learned response. This suggests the existence of a ceiling effect where hippocampal responding seems to support learning to a limited degree only, no matter how regular or efficient it is. In fact, in healthy young animals learning seems to be most efficient when the to-be-learned associations are presented randomly or in the absence of hippocampal \( \theta \) and with a long enough ITI (Nokia and Wikgren 2014). Our current and earlier results are at odds with some previous findings on enhanced learning and neural responses following \( \theta \)-contingent trace eyeblink conditioning in young healthy animals (Griffin et al. 2004; Darling et al. 2011). These discrepancies in results might be explained by differences in, for example, the algorithm for detecting \( \theta \) or the duration of the CS which here was 200 msec in comparison to 100 msec used in the studies cited above. It might be that the longer duration of the CS used here made its presentation less specific to a certain phase of the \( \theta \) oscillation as the duration of a single full cycle of a 6 Hz oscillation is \(< 200 \text{ msec}."

In addition to the effects of \( \theta \) phase on the encoding of incoming information we also studied its effects on the retrieval of already established memories. According to the theory of Hasselmo and colleagues (2002, 2014), during the peak of the \( \theta \) cycle recorded near the hippocampal fissure, entorhinal input is suppressed and the CA3 autoassociative network activated, which supports the retrieval of already encoded information. However, in the present study, there was no effect of \( \theta \) phase on memory retrieval in well-learned animals. Although hippocampal responses to the CS were, once again, temporally well-organized when presented to the trough of the \( \theta \) cycle and less organized when presented to the peak, conditioned responding at the behavioral level did not differ according to the timing of the CS relative to the fissure \( \theta \) phase. Thus, efficient hippocampal processing seems to be crucial only in the very early stage of learning, when the CS–US association is first realized and CRs start to emerge at an increasing rate (Prokasy 1984). It would seem that the hippocampus has only a modulatory, if any, role in the late stages of CR acquisition or in the retention of the CR, leaving other brain structures such as the prefrontal cortex (Weiss and Disterhoft 2011) and/or the cerebellum (Gould and Steinmetz 1996) in charge. To better pinpoint the timing of hippocampal dependence of learning, the effects of \( \theta \) phase-contingent stimulus presentation on memory retrieval should be tested earlier in the conditioning process, ideally at several different intervals from the onset of conditioning, in subjects otherwise trained irrespective of their neural state. It is also noteworthy that the theory by Hasselmo and colleagues (2002, 2014) was developed to explain mechanisms of memory retrieval and encoding during episodic memory modeled by spatial navigation tasks in rodents. Although also a form of episodic learning, eyeblink classical conditioning in rabbits might be governed by slightly different rules, which might explain the contradictions between our current results and the theory by Hasselmo and colleagues (2002); Hasselmo and Stern (2014).

In conclusion, to our knowledge, this is the first study to demonstrate that the timing of a peripheral stimulus to a certain phase of hippocampal \( \theta \) oscillation produces robust effects on the synchronization of neural responses and affects learning at the behavioral level. That is, the phase of the hippocampal \( \theta \) oscillation seems to be a means of regulating the processing of information in the brain up to a behaviorally relevant degree. Our results also support the notion of a time- and otherwise limited role for hippocampal processing in associative learning: high-amplitude, phase-locked hippocampal responses to the CS seem crucial only for the initial stage of classical conditioning, i.e., associating the CS with the unconditioned stimulus, and enhancing these responses does not automatically lead to better learning.

### Materials and Methods

#### Subjects

The subjects were 17 adult female New Zealand White rabbits (Lidköpings kaninfarm, Sweden) weighing \(~3.3 \text{ kg}\) at the time of surgery. The rabbits were housed in individual cages on the premises of the animal research unit of the University of Jyväskylä. Food and water were freely available, and room temperature and humidity were controlled. The rabbits were maintained on a 12/12 h light–dark cycle, with lights on at 8:00 a.m. All procedures were conducted during the light portion of the cycle. All the experimental procedures were implemented in accordance with Directive 2010/63/EU of the European Parliament and of the Council on the care and use of animals for research purposes.

#### Surgery

Subcutaneous injections of an analgesic solution (0.1 mL of 0.3 mg/mL buprenorphine [Temgesic, Schering-Plough Europe] diluted in 0.9 mL of 0.9% NaCl, dose: 2 mL) and of an anti-inflammatory drug (50 mg/mL carprofen [Rimadyl vet, Pfizer Inc. Animal Health], dose: 0.1 mL/kg) were administered \(>30 \text{ min}\) prior to surgery. The rabbits were anesthetized with an i.m. injection of ketamine–xylazine cocktail (7.8 mL of 50 mg/mL Ketaminol vet [Intervet International B.V.] mixed with 2.8 mL of 20 mg/mL Narcoxyl vet [Intervet International B.V.]). A dose of 0.8 mL/kg of the cocktail was injected i.m. before surgery. During surgery, additional doses of either the cocktail or ketamine alone were injected subcutaneously approximately every 20–30 min or as needed. At the beginning of surgery, the rabbit was placed in a stereotaxic instrument (Kopf Instruments) with the bregma positioned 1.5 mm higher than the lambda. Eye gel was administered to prevent the animal’s eyes from drying. A longitudinal incision was made to the scalp and four stainless-steel anchoring screws (5 mm anterior and 5 mm lateral to the bregma; 13 mm posterior and 5 mm lateral to the bregma) were attached to the skull. The screws were connected together and served as a reference for the electrophysiological recordings. Next, a piece of skull was removed above the left hippocampus and the dura cut to expose the surface of the brain. A 32-channel linear probe (A1 \(\times 32\)–10 mm-100–177, H32 package, NeuroNexus) attached to a microdrive (nDrive xL, NeuroNexus) was chronically implanted into the dorsal hippocampus 5 mm posterior, 5.5 mm lateral, and \(~4 \text{ mm}\) below the surface of the brain, aiming the tip of the probe at the dentate gyrus. The opening in the skull was sealed using Tissu-Sil (World Precision Instruments) silicone. Last, the probe and microdrive were cemented in place with dental acrylic. For three animals, instead of the linear probe, six monopolar recording electrodes made of Teflon-insulated stainless steel wire (bare diameter \(125 \mu \text{m}\)) mounted inside 27-gauge hypodermic stainless steel tubing were chronically implanted into the left dorsal hippocampus 5–6 mm posterior, 4–7 mm lateral, and 6.5–7.4 mm below the bregma, aiming at the hippocampal fissure and dentate gyrus. The data from these animals were combined with the data from the animals implanted with linear probes. Metoclopramide (dose 0.1 mL/kg, concentration 5 mg/mL; Primperan [Sanoﬁ Winthrop Industriel]) was injected subcutaneously immediately after surgery to facilitate normal feeding and drinking. Analgesic (buprenorphine, see above for details) was administered every 8 h for the next 24–48 h depending on the recovery rate of the animal.

#### Conditioning procedure

During the recordings, the rabbits were placed in a Plexiglas retraining box allowing free movement of the head and located...
in a ventilated, electrically insulated, and sound-attenuated conditioning chamber. A fan located inside the conditioning chamber behind the rabbit created a steady background noise of ~65 dB. At least 1 wk was allowed for postsurgical recovery before commencing the experiment. During the recovery period, the animals were habituated to the recording chamber and neural signals recorded briefly (10–20 min) to adjust the position of the linear probe, using the microdrive. The probe was positioned so that CA1 ripples, θ and CA3 ripples were visible.

LabView (National Instruments) and E-Prime software (Psychology Software Tools Inc.) were used to control the presentation of the stimuli. Briefly, the signal from one electrode site near the hippocampal fissure was monitored online in 1-s sweeps refreshed every 50 msec. For each sweep, the Fast Fourier Transform was calculated with a resolution of 1 Hz. The θ ratio (%), was calculated as the ratio between the power of the signal near the hippocampal fissure and CA3 ripples was visible.

Tone-alone session: testing response modulation according to θ phase

To study response modulation as a function of hippocampal θ phase, before conditioning, an 80-dB, 4-kHz, 200-msec tone later be used to be assessed as the CS was presented 300 times (minimum intertrial interval (ITI) 10 s). For five animals later assigned to the experimental groups, the tone was presented during periods of dominant θ (T+) recorded from the fissure. Stimuli were delivered when the θ ratio exceeded 80%. For six animals later assigned to the experimental groups, tones were presented irrespective of their brain state, using the ITIs from the first five animals (to which the tone was presented contingent on a high θ ratio). For the animals assigned to the yoked control group, stimuli were presented irrespective of their brain state. The CS-alone treatment type (T+ versus random) was included as a covariate in the repeated-measures ANOVAs when examining differences between the experimental groups and changes across training.

θ phase–contingent trace eyeblink conditioning (Peak/Trough)

During conditioning, the CS, a 80-dB, 4-kHz, 200-msec tone, was paired with the unconditioned stimulus (US), a 100-msec air puff toward the eye. A 500-msec trace period was used, creating a 700-msec onset-to-onset interval. Sixty trials per session were conducted with a minimum ITI of 35 s. For one group of animals, the CS was timed to commence at the trough of hippocampal fissure θ (Trough, n = 5) and for the other group it was timed to start at the θ peak (Peak, n = 6). Examples of the timing of the conditioning stimuli relative to hippocampal θ are presented in Figure 1B. Grouping was random. Using LabView, the CS was timed to commence at a certain phase of the θ cycle by using a combination of the θ ratio (>60%) and simple threshold triggering: the signal had to pass through two threshold values either on its way up (rising) or on its way down (falling). Although the algorithm was very simple, and by means perfect, the setup worked well. The instantaneous phase of the θ cycle at CS onset was -0.03 radians (SEM 0.05) in the Peak group and 3.01 (SEM 0.05) radians in the Trough group during the first conditioning session, indicating very good accuracy in timing. (Note that for the trough group, negative phase values were corrected (x + 2π) so that the distribution peak was set at around π.) A group of yoked control (YC, n = 6) animals were trained together with animals in the Peak (n = 3) and Trough (n = 3) groups, that is, the YC group received conditioning trials irrespective of their neural state. Animals were assigned to the YC group on the basis of broken electrodes (no signal). Ten conditioning sessions were carried out on consecutive days.

Trace eyeblink conditioning contingent on the absence of θ (T–)

After the initial training period, conditioning was continued for another six daily sessions, but now trials were only triggered when the animal in the experimental group (Peak/Trough) exhibited low θ power (T–, θ ratio <35%).

Testing the effect of θ phase on memory and learned performance

Finally, the effects of fissure θ phase on retrieval of the memory trace/performance of the conditioned response (CR) (Hasselmo et al. 2002; Hasselmo and Stern 2014) were tested. Animals were presented with 60 paired trials, of which 30 were timed to commence at the peak and 30 at the trough of fissure θ, in a random order. Another test session was performed the next day to accumulate 60 trials delivered to the peak and 60 trials delivered to the trough of θ.

Recordings and data analysis

Bipolar electromyogram (EMG) was recorded using stainless steel wire hooks placed around the right upper and lower eyelids for the duration of the training session. To acquire neural measures, a low-noise preamplifier (MP34 or MP32, MultiChannel Systems (MCS)) was directly attached to the electrode coupler anchored with dental acrylic to the rabbit’s head. A flexible, insulated cable was used to connect the animal to the filter amplifier (FA64L, filter: 1–5000 Hz, MCS). All signals were digitized (USB- ME-64 System, MCS) and recorded with Mc_Rack software (MCS), using a 20-kHz sampling rate. Finally, all signals were digitally band-pass filtered between 1 and 500 Hz (high-pass: RC, low-pass: fourth-order Bessel) and stored using a 2-kHz sampling rate. MATLAB (The MathWorks Inc.), and SPSS (SPSS Inc.) were used for offline data analysis.

Eyeblinks

The EMG signal was high-pass filtered off-line (>100 Hz) and Hilbert-transformed. An envelope curve following the peaks of the signal was calculated. Baseline EMG activity was defined for each animal and session as the mean of the peak EMG amplitude during a 500-msec pre-CS period (MEANpre). Also determined was the mean of the standard deviation of the EMG activity during the 500-msec pre-CS period (SDpre). Eyeblinks were defined as EMG activity exceeding a threshold of [MEANpre + 4 × SDpre] for at least 10 msec. Trials with eyeblinks during the 100-msec period immediately preceding CS onset were rejected. Eyeblinks during the latter half (250-msec period) of the 500-msec trace period were counted as conditioned responses. As in our previous studies (Nokia and Wikgren 2014) on trace eyeblink conditioning, the learning criterion were considered to be met when the subject performed ≥60% CRs during at least one conditioning session. Learning rate was quantified as the cumulative percentage of CRs, the number of trials to the fifth CR and the number of trials to meet the criterion of eight CRs on nine consecutive trials, which has been used to indicate asymptotic learning (see, for example, Berry and Thompson 1978).

Relative magnitude of hippocampal θ-band (4–8 Hz) oscillations: θ ratio

θ ratio (Nokia et al. 2009) was obtained from a 5-min baseline recording conducted immediately prior to the first conditioning session. To this end, the hippocampal fissure signal was analyzed in 1500-msec sweeps using the FFT. From the FFT result, the ratio (%) of the power of the signal at the θ band (4–8 Hz) compared with that at the θ and delta bands (1–8 Hz) was calculated. To study the relative amplitude of the θ-band responses to the conditioning stimuli, the hippocampal θ ratio was calculated from 700-msec period immediately following CS onset. For statistical analysis, the θ ratio during the CS and subsequent trace period (700 msec) was averaged over sessions (correlation with learning) and then over blocks of two sessions (changes across training and differences between groups).

Phase-locking of hippocampal θ-band (4–8 Hz) responses

To assess the temporal accuracy of the θ-band responses to the conditioning stimuli, a phase-locking value (PLV) (Palva et al.
trode locations were determined with the help of a microscope. Dried, and stained with Prussian blue and cresyl violet. The eneral days. The brain was coronally sectioned with a vibratome into portions (%) of animals that learned in each group. Pearson’s cor-

Statistical analyses

Repeated-measures analysis of variance (ANOVA), with training blocks of two sessions as a within-subjects factor and group as a between-subjects factor, was used to analyze changes across conditioning. Type of CS-alone treatment (random versus T+) was included as a two-level covariate (0/1). Whenever a significant interaction of block and group emerged, separate repeated-measures ANOVAs were conducted for each group, using blocks as a within-subjects factor. Greenhouse–Geiser corrected P-values are reported when the sphericity assumption was violated according to Mauchly’s test. One-way ANOVA was used in group comparisons when single variables were tested. Bonferroni corrected P-values were used for post hoc comparisons. Binomial test was used to compare the proportions (%) of animals that learned in each group. Pearson’s correlation coefficient was used to analyze the connection between hippocampal θ-band responses to the CS and learning. Finally, paired samples t-tests were used to analyze differences within subjects.

Histology

Rabbits were anesthetized with i.m. injection of ketamine–xylazine cocktail and then overdosed with an i.v. injection of pen-tobarbital (Mebunat vet, Orion-Yhtymä Oyj). Next, the brain was perfused with physiological saline followed by 9% formalin solution through the ascending aorta. The locations of the electrode tips were marked by passing a DC current (200 μA, 5 sec) through them. The brain was then removed and stored in formalin for several days. The brain was coronally sectioned with a vibratome into 60-μm-thick slices. The slices were attached to gelatinized slides, dried, and stained with Prussian blue and cresyl violet. The electrode locations were determined with the help of a microscope.

Acknowledgments
