ABSTRACT: The synthesis and characterization of a stable, acyclic two-coordinate silylene, Si(SArMe3)2, (ArMe3 = C6H5-2,6(C6H5-2,4,6-Me3)2) by reduction of Br2Si(SArMe3), with a magnesium(I) reductant is described. It features a v-shaped silicon coordination with a S-Si-S angle of 90.51(2)° and an average S-Si distance of 2.158(3) Å. Although it reacts readily with an alkyl halide, it does not react with hydrogen under ambient conditions probably as a result of the ca. 4.3 eV energy difference between the frontier silicon lone pair and 3p orbitals.

For several decades, silylenes, the silicon analogues of carbenes, had been known only as transient species either in the gas phase, in solution, or trapped in frozen matrices.1, 2, 3 In 1986, Jutzi and coworkers reported the isolation of decamethylsilicocene which was the first monomeric, divalent silicon(II) compound that was stable at room temperature.4 The formally ten-coordinate Si(η5-C5Me5)2 exists as two conformers; a centrosymmetric species with parallel C5Me5 rings or a bent form with a 25.3° interplanar angle. In 1994, the synthesis and structure of a two-coordinate, N-heterocyclic silylene, in which silicon is single bonded to two nitrogens, was reported by West and coworkers.5 Currently, numerous stable divalent silicon species are known6,8 but strictly two-coordinate species invariably involve silicon as part of a ring7 with the most common being the aforementioned N-heterocyclic silylenes.9 A cyclic alkyl silylene, which is stable at 0 °C, was reported by Kira but it isomerizes in solution via a 1,2-migration of an adjacent trimethylsilyl group to give a silene.10 Other examples include the bisamido derivative Si[NPr(2,6)(i-Pr)2]2, which exists in a monomer/dimer equilibrium with the SiSi double-bonded disilene [Si(NP(2,6)(i-Pr)2)2],12 as well as Si[N(SiMe3)2]2, which persists for more than 12 h at -20 °C but decomposes into a complex mixture of products at increased temperatures.9 We now report that the reduction of the silicon(IV) precursor, Br2Si(SArMe3), (1) (ArMe3 = C6H5-2,6(C6H5-2,4,6-Me3)2), affords the silicon dithiolate, Si(SArMe3)2, (2), which has a monomeric, two-coordinate structure and is an example of a stable acyclic two-coordinate silylene. In addition, the Si(IV) bisthiolatosilane 3 was prepared in order to compare its structural and spectroscopic parameters with those of 2. Furthermore, 2 was characterized by its derivatization with MeI to afford Si(Me)(I)(SArMe3)2 (4). An overview of the synthesis is given in Scheme 1.

The precursor, 1, was obtained by reaction of SiBr4 with (LiSArMe3)2, in diethyl ether.14,15 and 2 was synthesized by reduction with Jones’ complex (IMesMg), (IMes = [(2,4,6-trimethylphenyl)NC(CH3)2]CH) complex in toluene.16,17 The yellow solution of Br2Si(SArMe3), became darker with concomitant precipitation of IMesMgBr, upon stirring for 2 days at ca. 25°C. Workup afforded colorless crystals of 2 in moderate yield (51%). The silylene, 2, was found to be stable up to 146 °C. The X-ray crystal structure of 2 (Figure 1) showed that the silicon bonds to two thiolate sulfurs with a S-Si-S angle of 90.52(19)°. The Si-S distances are 2.1607(5) and 2.1560(5) Å and the Si-S-C angles are 100.85(5) and 105.01(4)°. The closest other approaches to silicon involving C(7) and C(12) at 3.004(1) and 3.232(1) Å as well as C(31) and C(32) at 3.052(1) and 3.293(1) Å respectively. The Si-centroid distances to the rings are 3.453 and 3.419 Å.

Figure 1. Thermal ellipsoid (30%) plot of 2 without H atoms. Selected bond lengths (Å) and angles (°): Si(1)-
The Si-S bonds are mainly single in character as indicated by the calculated WBI of 0.95 for the Si-S bonds\(^a\) although weak Si-S n-bonding may exist as indicated by computations (vide infra) and the low average torsion angle (13.4(2.1)°) between the coordination plane of silicon and those at the sulfurs.\(^{7,29,30}\) The Si-S distances in 2 are longer than those reported for in the bisthiolatosilylene- platinum complex, trans-(Cy\(_3\))P\(_2\)Pt(H)Si(SE\(_2\))OTf, by ca. 0.07 Å,\(^{29}\) but are comparable to those predicted for 1,2-ethanedisulfide silylene.\(^{20}\) DFT Calculations,\(^{29}\) using the hybrid PBE1PBE exchange-correlation functional\(^{22}\) in combination with the def2-TZVP basis set for the whole molecule of 2 and 3,\(^{23}\) afforded structural parameters very close to those experimentally measured (Table 1).

The \(^{29}\)Si NMR spectrum of 2 revealed a downfield signal at \(\delta = 285.5\) (cf. \(\delta = -23.1\) for 1). The signal is further downfield than those of cyclic amidosilylenes (\(\delta = 78-119\)),\(^{3}\) Dries’s ylide-stabilized silylenes (\(\delta = 212.4, 213.3\))\(^{37}\) and the thermally unstable silylene, Si[NSiMe\(_3\)]\(_3\). (\(\delta = 223.9\)),\(^{31}\) however, it is well upfield that reported for the dialkylsilylene (\(\delta = 567\)).\(^{11}\) The downfield shift of 2 is consistent with a two-coordinate silicon since an increased coordination number produces a significant upfield shift as observed in (C\(_5\)H\(_2\)-2,6(C\(_5\)H\(_2\))-2,4,6-Pr\(_3\))\(_2\)Si(\(\eta^3\)-C\(_5\)Me\(_5\)) (\(\delta = 51.6\)) (four coordinate silicon)\(^{24}\) and decamethylsilicocene (\(\delta = -577\)) (ten coordinate silicon).\(^{4,25}\) The \(^1\)H and \(^13\)C NMR spectra suggest free-rotation around the C-S bond due to the observation of only two signals for the O- and P- methyl groups of the flanking arenne rings.

The electronic transitions were calculated by the TD-DFT approach using the same functional-basis set combination as employed in the geometry optimization.\(^{21-23}\) The Kohn-Sham orbitals for 2 are shown in Figure 2. The calculations reveal several excitations at wavelengths between 250-400 nm although only the five strongest predicted absorptions are discussed here. The calculated values may be compared to the four transitions observed in the electronic spectrum. The HOMO-LUMO (silicon n \(\rightarrow\) 3p) absorption appears as a shoulder at 382 nm (\(\epsilon = 8900\) M\(^{-1}\) cm\(^{-1}\)).\(^{26}\) A more intense absorption at 318 nm (\(\epsilon = 23,000\) M\(^{-1}\) cm\(^{-1}\)) (HOMO-1 \(\rightarrow\) LUMO) corresponds to a transition from a sulfur lone pair to the silicon 3p orbital. The calculated absorption at 296 nm corresponds to the HOMO \(\rightarrow\) LUMO+1 transition but is partly obscured by other absorptions that are close in energy. It arises from transitions between the silicon lone pair to the arene \(\pi^*\) orbitals. The absorptions at 291 (\(\epsilon = 20,000\) M\(^{-1}\) cm\(^{-1}\)) and 269 (\(\epsilon = 25,000\) M\(^{-1}\) cm\(^{-1}\)) nm are due to an arene \(\pi\) to silicon \(p\) transition and from both silicon and sulfur lone pairs to arene \(\pi^*\) orbitals respectively. A series of very intense absorptions, centered at ca. 220 nm, correspond to arene \(\pi\) \(\rightarrow\) \(\pi^*\) transitions that partially mask the absorptions at 291 and 269 nm. Overall, the experimental and computational values for the spectral data are in good agreement (associated content).

The bisthiolatosilane, 3, (Figure 3) was obtained from HSiCl\(_3\) and (LiSAr\(_{2}\)). The structural data reveal a relatively close resemblance between the structural parameters for the Si[Si(C\(_3\)ips)]\(_2\) moiety and those of silylene 2, with very similar Si-S distances and a small, ca. 3°, difference in the S-Si-S bond angle. The Si-Centroid distances differ by ca. 0.1 Å. However, the compounds 2 and 3 were unequivocally distinguished by the location and refinement of the two Si-H hydrogens in 3. The presence of the Si-H hydrogens was also confirmed by the observation of a 1:2:3 triplet signal in the \(^{29}\)Si NMR spectrum at \(\delta = -13.2\) (\(\delta_{\text{SiH}} = 256\) Hz).\(^{27}\) In addition, the Si-H signal in the \(^1\)H NMR spectrum was observed at 4.11 ppm and two satellite signals corresponding to the natural abundance of \(^{29}\)Si were also identified (\(\delta_{\text{SiH}} = 256\) Hz). Two partially overlapped absorptions at 2182 and 2168 cm\(^{-1}\) in the IR spectrum are characteristic of a and b Si-H stretching modes.\(^{25,28}\) The addition of MeI to 2 afforded the iodo-methylbisthiolatosilane, 4.\(^{6,29}\) Its \(^{29}\)Si NMR spectrum revealed an upfield quartet at \(\delta = -5.88\) (\(\delta_{\text{SiH}} = 8.3\) Hz) A methyl group signal at \(\delta = 2.01\) (\(\delta_{\text{SiH}} = 8.7\) Hz) in the \(^1\)H NMR spectrum and a signal at \(\delta = 11.39\) in the \(^13\)C NMR spectrum is comparable to compounds with similar moieties.\(^{30,31}\)

Attempts to react 2 directly with hydrogen gas to afford 3 were unsuccessful, possibly because of the relatively high electronegativity of the thiolate substituents which increase the energy separation (4.26eV) of the silicon lone pair and the 3p orbitals and make the synergic interaction between the frontier orbitals of 2 and H\(_2\) less likely. In effect, the electronegative character of the thiolate ligands is a key factor both in the stability of 2 (with some help from Si-S n-bonding), and its reluctance to react with hydrogen. Geometric constraints of the ligands may also hinder the reactivity of 2.\(^{25}\)
In summary, a thermally stable, two-coordinate, acyclic silylene stabilized by a bulky terphenyl thiolate ligand has been synthesized and characterized. Until now, stable two-coordinate silylenes have been limited to cyclic systems in which silicon is bound to elements of the 2nd row of the periodic table. Future work will involve the investigation of further reactions of 2 as well as those of its heavier element analogues.

Note: The synthesis and structure of another type of acyclic silylene is given in the preceding paper.33
