The splitting of the simplest non-polar molecule dihydrogen (H2) is a critical chemical reaction that is most commonly accomplished by a transition metal center in homogeneous, heterogeneous or biological catalysts via homolytic oxidative addition or heterolytic processes.1 Recently, interest in more environmentally benign, transition metal-free systems for activation of dihydrogen2-4 has spiked,5 primarily spurred by the development of the “Frustrated Lewis Pairs” (FLPs) concept.6-8 In FLPs, Lewis acid/base combinations sterically prevented from forming strong classical adducts are capable of heterolytically activating H2. Highly Lewis acidic perfluoroarylboranes,9,10 such as B(C6F5)3, are typically employed as the hydride acceptor, while bulky phosphines,11 amines/imines12-15 or carbene16-18 serve as the Lewis base proton acceptor.

The mechanistic details of hydrogen activation by FLPs are still a subject of debate, although computational investigations point to an “encounter complex” (I, Scheme 1) stabilized by non-covalent interactions and dispersion forces16-17 that creates an electric field in the pocket of the FLP where a dative bond would form in a satisfied Lewis acid/base pair. This electric field polarizes H2 leading to cleavage of the H-H bond.18 Despite the in silico support for this picture, spectroscopic evidence for the encounter complex is lacking.

An alternate view involves an adduct between borane and H2 (II), related to transition metal H2 sigma complexes.19 Intermediate II could be deprotonated directly, or proceed to III via heterolytic addition of H2 across a B-C bond, an intermediate analogous to protonated fluorobenzenes.20-21 This has been proposed as the initial step in the addition of H2 to Stephan’s seminal phosphinoborane hydrogen activation system,4 and supported computationally.22 This mechanism is conceptually related to that developed for the B(C6F5)3-catalyzed hydrosilation of carbonyl23-25 and imine26 functions and the dehydrosilation of alcohols.27 Here, the Lewis acidic borane activates the silane towards nucleophilic attack by the substrate by partially abstracting the silane hydrogen via a borane/silane adduct related to II. While the mechanism of B(C6F5)3 catalyzed hydrosilation is well established, the involvement of II in FLP H2 splitting remains unproven even though computations suggest II is energetically viable relative to the reactants.6

Mechanistic details aside, it is clear that a high level of Lewis acidity at the boron center is required29 in order to achieve hydrogen activation in these systems; unfluorinated triphenylborane, B(C6H5)3, for example, is much less effective as an FLP partner.5 Recently, we reported the synthesis and characterization of perfluoropentaphenyl borole, 1,29 a new perfluoroarylborane with exceptional Lewis acid strength as a consequence of both fluoroaryl substitution and the antiaromaticity of the 4π borole ring.30 Its reactivity in the context of the FLP paradigm was therefore worthy of exploration.

Borole 1 is sparingly soluble in non-donor solvents and even weakly Lewis basic solvents form adducts.29 Halogenated solvents are most useful, but mixtures of I and ‘BuP in CD3Cl exhibit reactions that involve chloride transfer to I, indicative of C-Cl bond activation. In CD3Br, however, I and ‘BuP do not activate solvent and no indication of conventional adduct formation is apparent, either spectroscopically or visually (the intense color of the reaction product mixture). Exposure of this mixture to H2, however, resulted in a rapid reaction. Surprisingly, a mixture of products was observed and the expected phosphonium borate ion pair [I(C2F5)3]C6B(H/C6F5)[HP(‘Bu)5]. (2), was a minor component (<15%) of the reaction product mixture.

This observation led us to investigate the reactivity of I with H2 in the absence of ‘BuP. Rapid reaction in CD3Cl, CD3Br or C6D6 (less than one minute) was indicated by the decolorization of these solutions or suspensions; indeed, even exposure of microcrystalline solid samples of I to an...
atmosphere of H\textsubscript{2} resulted in conversion to an off-white solid within 20 minutes.

The products are the two major species observed in the reaction performed in the presence of Bu3P and were identified as the cis and trans isomers of the boracyclopent-3-ene heterocycles 3 that result upon formal addition of hydrogen to the carbons \(\alpha \) to boron in borole 1 (Scheme 2). This was deduced on the basis of multinuclear NMR spectroscopy, derivatization to the pyridine adducts and via X-ray crystallographic characterization of cis-3 and trans-3-py.

The \(^{11}\text{B}[\text{H}]\) NMR spectrum of products 3 shows a broad resonance at 78.5±1.0 ppm, consistent with a three coordinate borane center and distinct from the 66.0 ppm resonance at 78.5±1.0 ppm, consistent with a three coordinate isomerization to the thermodynamic mixture of pyridine. For the reaction of isomers occurs by reversible dissociation and recooordination experiments, the kinetically favored isomer of intensity of the resonance at 4.09 ppm. On the basis of nOe eight hours, this signal grows in until present at half the 4.09 and 4.98 ppm, the latter barely observable initially. Over changes in the spectrum upon addition of pyridine (Fig. S1). The signal at 5.13 ppm splits into two equal intensity peaks at 5.67 and 5.06 ppm for the now inequivalent protons of 3. The signal at 5.13 ppm splits into two equal intensity peaks at 5.67 and 5.06 ppm for the now inequivalent protons of 3. The signal at 5.13 ppm splits into two equal intensity peaks at 5.67 and 5.06 ppm for the now inequivalent protons of 3. The signal at 5.13 ppm splits into two equal intensity peaks at 5.67 and 5.06 ppm for the now inequivalent protons of 3.

This was deduced on the basis of multinuclear NMR spectroscopy, derivatization to the pyridine adducts and via X-ray crystallographic characterization of cis-3 and trans-3-py. The \(^{11}\text{B}[\text{H}]\) NMR spectrum (Fig. S1) shows two singlets in a 2:1 ratio at 5.14 and 4.83 ppm assigned to the trans and cis isomers of 3, respectively, on the basis of the changes in the spectrum upon addition of pyridine (Fig. S1). The signal at 5.13 ppm splits into two equal intensity peaks at 5.67 and 5.06 ppm for the now inequivalent protons of trans-3-py, while at 4.82 ppm transforms into two singlets at 4.09 and 4.98 ppm, the latter barely observable initially. Over eight hours, this signal grows in until present at half the intensity of the resonance at 4.09 ppm. On the basis of nOe experiments, the kinetically favored isomer of cis-3-py is that with pyridine oriented cis to the two a protons (Fig S2). Isomerization to the thermodynamic mixture of cis-3-py isomers occurs by reversible dissociation and recoordination of pyridine. For the reaction of 1 with H\textsubscript{2} in solution, trans-3 is kinetically favored, but for reactions of solid 1 with H\textsubscript{2}, cis-3 is the dominant product, by a 10:1 margin. DFT computations show that the LUMO of 1 is associated with the boron center and the two \(\alpha \) carbons, (Fig. S4) but the low solubility of 1 has precluded low temperature NMR experiments aimed at observing an H\textsubscript{2} adduct of 1 spectroscopically. However, DFT computations locate a minimized energy structure for the H\textsubscript{2} adduct of 1 that is only 0.5 kcal mol\(^{-1}\) less stable than the reactants (Fig. S5). Since the H\textsubscript{2} adduct of B(C\textsubscript{5}F\textsubscript{5})\textsubscript{2}, itself (i.e. II) reacts only by dissociation of H\textsubscript{2} (unless there is a proton acceptor on one of the fluorinated aryl rings\textsuperscript{3}), it appears that disruption of antiaromaticity in the borole ring\textsuperscript{3} provides a driving force for the remarkably facile reaction of 1 with H\textsubscript{2} to give compounds 3. The energetic destabilization of 4\textsubscript{t} five membered borole rings compared to related aromatic systems has been estimated to be \(\approx\)10-20 kcal mol\(^{-1}\),\textsuperscript{3,33-34} thus, the combination of antiaromaticity and high Lewis acidity in 1 leads to rapid H-H bond activation in the absence of an external Lewis base partner. Indeed, the extra driving force provided by antiaromaticity permits H\textsubscript{2} activation in more weakly Lewis acidic pentaarylboroles; the reaction of unfluorinated pentaphenylborole\textsuperscript{4} with H\textsubscript{2}, although slower, produces cis-5 and trans-5 in a 1.0:4.3 ratio over 2-3 hours (Scheme 3). Interestingly, no H\textsubscript{2} adduct with 4 is found by DFT calculations, suggesting that here, H\textsubscript{2} binding to the less Lewis acidic boron center may be rate limiting.

The structures of cis-3 and trans-3-py were confirmed by X-ray crystallography,\textsuperscript{12} a thermal ellipsoid diagram of the former compound is shown in Fig. 1, with selected metrical parameters; that of the latter is given in the SI (Fig. S3). The C1B ring in cis-3 features a trigonal planar boron center (sum of angles = 359.2(6)\textdegree), and a C-C double bond between C2 and C3 (1.326(5)\AA{}). The hydrogen atoms on C1 and C4 were located on the difference map and their positions refined; the C1 and C4 carbons are clearly pyramidalized (sum of non-hydrogen angles about C1: 331.9(5)\textdegree; C4: 340.6(5)\textdegree) and the \(\alpha \) carbon C\textsubscript{3}F\textsubscript{5} rings lie below the C\textsubscript{6}B plane. Although the trans-3 isomer can be produced in pure form photochemically, suitable crystals were not obtained; instead, this isomer’s structure was confirmed via characterization of its pyridine adduct. The hydrogen atoms on C1 and C4 were again located and refined and their positioning trans to each other on the C\textsubscript{6}B plane.

The reaction between 1 and H\textsubscript{2} in the absence of an external base shows that 1 is capable of forming a reactive adduct with H\textsubscript{2}. DFT computations show that the LUMO of 1 is associated with the boron center and the two \(\alpha \) carbons, (Fig. S4) but the low solubility of 1 has precluded low temperature NMR experiments aimed at observing an H\textsubscript{2} adduct of 1 spectroscopically. However, DFT computations locate a minimized energy structure for the H\textsubscript{2} adduct of 1 that is only 0.5 kcal mol\(^{-1}\) less stable than the reactants (Fig. S5). Since the H\textsubscript{2} adduct of B(C\textsubscript{5}F\textsubscript{5})\textsubscript{2}, itself (i.e. II) reacts only by dissociation of H\textsubscript{2} (unless there is a proton acceptor on one of the fluorinated aryl rings\textsuperscript{3}), it appears that disruption of antiaromaticity in the borole ring\textsuperscript{3} provides a driving force for the remarkably facile reaction of 1 with H\textsubscript{2} to give compounds 3. The energetic destabilization of 4\textsubscript{t} five membered borole rings compared to related aromatic systems has been estimated to be \(\approx\)10-20 kcal mol\(^{-1}\),\textsuperscript{3,33-34} thus, the combination of antiaromaticity and high Lewis acidity in 1 leads to rapid H-H bond activation in the absence of an external Lewis base partner. Indeed, the extra driving force provided by antiaromaticity permits H\textsubscript{2} activation in more weakly Lewis acidic pentaarylboroles; the reaction of unfluorinated pentaphenylborole\textsuperscript{4} with H\textsubscript{2}, although slower, produces cis-5 and trans-5 in a 1.0:4.3 ratio over 2-3 hours (Scheme 3). Interestingly, no H\textsubscript{2} adduct with 4 is found by DFT calculations, suggesting that here, H\textsubscript{2} binding to the less Lewis acidic boron center may be rate limiting.

The structures of cis-3 and trans-3-py were confirmed by X-ray crystallography,\textsuperscript{12} a thermal ellipsoid diagram of the

Figure 1. Thermal ellipsoid diagram (50%) of cis-3. Selected bond distances (Å): B1-C1, 1.585(6); C1-C2, 1.533(5); C2-C3, 1.326(5); C3-C4, 1.529(5); B1-C4, 1.586(6). Selected bond angles (\(\textdegree\)): C1-B1-C5, 124.4(3); C1-B1-C4, 106.2(3); C4-B1-C5, 128.6(4); B1-C1-C11, 115.7(3); B1-C1-C2, 103.1(3); C2-C1-C11, 113.1(3); B1-C4-C29, 124.3(3); B1-C4-C3, 102.8(3); C3-C4-C29, 113.5(3).
Attempts to reverse the addition of H₂ to Lewis acidic borole 1 thermally or photochemically were unsuccessful, and no deuterium incorporation into compounds 3 under any conditions upon exposure of their solutions to four atmospheres of D₂ was observed. Interestingly, when mixtures of cis-trans-3 were treated with Bu₃P (one equivalent per boron), conversion to the phosphonium borates 2 and 2' occurred (Scheme 4). Isomer 2' is the thermodynamic product of this reaction; pure samples exhibit ¹H NMR spectral signature resonances for the P-H (5.02 ppm, ¹J₉H = 426 Hz) and C-H (broad, 7.16 ppm, ¹J₁₉C = 149.3 Hz) protons. Furthermore, 2' exhibits a resonance at 169.9 ppm in the ¹³C NMR spectrum (1:1:1:1 quartet, ¹J₁₉C = 56 Hz) and resonances for four equivalent C₁₋₅ groups in the ¹⁹F NMR spectrum, in the expected 2:1:1:1 ratio. Likely, this reaction is initiated by direct deprotonation of a benzylic proton in boracies 3 by the phosphate base, rather than reversible formation of the H₂ adduct of 1 from 3. Nonetheless, conversion of cis-trans-3 to hydrido borate 2 suggests a possible H₂ delivery pathway via this ion pair⁴ using catalytic amounts of a bulky Lewis base.

In summary, we report a facile metal-free hydrogen splitting reaction at Lewis acidic, antiaromatic pentaarylbolore boron centers. The details of the mechanism of the reaction are yet to be determined, but the presence of the trans isomers of 3 and 5 as the major isomer in solution suggests that the H₂ adducts under go B-C₆ bond cleavage, followed by rapid cyclization to a mixture of boracyclo-3-ene products (Scheme 5). Photochemically generated cis-1,3-buta-1-3-dienylboranes similar to those shown in the Scheme have been shown to rapidly cyclize to boracyclo-3-enes.⁵⁻⁹ That this reaction occurs so rapidly in the absence of a frustrated Lewis base partner has implications for the mechanism of H₂ splitting by FLPs. Kinetic, thermodynamic and computational investigations that will address these issues in detail are underway; the greater solubility of unfluorinated pentaphenylborole 4, and the more forgiving timescale of its reaction with H₂, make it ideal for further study.

ACKNOWLEDGMENT. Supported by the Natural Sciences and Engineering Research Council (NSERC) of Canada, an NSERC Graduate Scholarship (L.G.M) and an Alberta Innovates Studentship (L.G.M.), the Academy of Finland and the University of Jyväskylä.

Supporting Information Available. Crystallographic data files for cis-3 and trans-3-py, additional experimental, spectroscopic and computational details.
