Ammonia Activation by a Nickel NCN-Pincer Complex featuring a Non-Innocent N-Heterocyclic Carbene: Ammine and Amido Complexes in Equilibrium**

Rudy M. Brown, Javier Borau Garcia, Juuso Valjus, Christopher J. Roberts, Heikki M. Tuononen, Masood Parvez, and Roland Roesler*

Abstract: An NCN-pincer complex of nickel(0), 3, featuring a six-membered N-heterocyclic carbene (NHC) central platform and amidine pendant arms, was synthesized by protonation of its nickel(II) precursor, 2. It retained Cl⁻ in the square planar coordination sphere of nickel and was expected to be highly susceptible to oxidative addition reactions. Complex 3 rapidly activated ammonia at room temperature, in a ligand-assisted process where the carbene carbon played the unprecedented role of proton acceptor. For the first time, the coordinated (ammine, 4) and activated (amido, 5) species were observed together in solution, in a solvent-dependent equilibrium. A structural analysis of 2 and 3 provided insight into the highly unusual, non-innocent behaviour of the NHC ligand.

The activation of ammonia at metal centers is believed to play a crucial step in the catalytic functionalization of organic substrates, most notably olefins. Unfortunately, conducting this reaction with a Lewis base as a substrate poses substantial difficulties related to the activation-coordination equilibrium, which in the vast majority of cases is completely shifted in favor of the latter. Early work on ammonia activation involved TiCl₂ by Armor and ZrCl₄ by Bercaw,² as well as Os₂(CO)₁₂ by Lewis and Süss-Fink.³ Iridium took center stage in the activation of ammonia starting with Milstein’s reports of oxidative addition of the N-H bonds at Ir² to yield dinuclear, bridging amido complexes Lₙ(H)(Ir(H-NH₂))₂Ir(H-L).⁴ Similarly chemistry was also investigated by Braun.⁵ Another significant development was the introduction of pincer complexes by Hartwig and later Turcuilet, who described the activation of ammonia on Ir² PDP and PPSIr pincer complexes, respectively, to yield mononuclear, terminal L(H)Ir(μ-NH₂)₂ derivatives.⁶ Also notable is the homolytic ammonia activation by a dinuclear Pd² PNP pincer complex, reported by Ozerov, where a terminal Lpd²-NH₂ species was obtained along with Lpd²-H.⁷

Ammonia activation via metathesis, without formally changing the oxidation state of the metal, is well documented on several metals including Ru and Ir⁸, but can pose problems in terms of catalysis because the hydrogen is removed from the catalytic site. Milstein showed evidence for the heterolytic, deprotonative N-H bond activation of ammonia using a Ru³ complex incorporating non-innocent PNP pincer ligands, without observing the corresponding RuL²⁻NH₂ species.⁹ The similar, ligand-assisted cleavage of the N-H bond in ammonia by an Ir² complex featuring a pyridyl-based PNP pincer ligand, to give a terminal LIr²-NH₂ species, was described by Yoshihazawa and Ozawa.¹⁰ A related ligand-assisted ammonia activation reaction was reported by Kuwata and Ikariya on a dinuclear LIr²(μ-H)(μ-NH²)Ir²L²⁻ compound, resulting in the formation of LIr²(μ-H)(μ-NH₂)Ir²L²⁻.¹¹ Piers recently disclosed the use of a carbene-based PCP-pincer complex of Ni² for the ligand-assisted activation of ammonia to give a terminal LNi²-NH₂ product.¹² Noteworthy are also the remarkable progress made in the activation of ammonia by main group systems.¹³ The activation of the N-H bond in ammonia proved to be highly sensitive to the nature of the catalyst,¹⁴ with the ammine-amide equilibrium being completely shifted upon changing the metal from rhodium (ammine) to iridium (amide) for the same ligand system.¹⁵ Moreover, the nature of the phosphine ligand was shown to have similar effects in iridium complexes.¹⁶ Homogeneous catalytic hydrosilation with ammonia remains a major challenge, and notable progress towards this goal was the stoichiometric, intramolecular hydrosilation of the coordinated ligand in an iridium amide complex.¹⁷

Continuing our investigations of ammonia activation on pincer complexes incorporating NHC scaffolds, we report herein the reversible, ligand-assisted activation of ammonia on a Ni² – NCN pincer complex.

Pro-ligand 1 is similar to those reported by Byers and Lavoie and was prepared by the stepwise functionalization of 1,4,5,6-tetrahydropyrimidine with N-Dipp-benzimidoyl chloride (Dipp =
2,6-diisopropylphenyl), using a modification of a reported procedure. Its room temperature reaction with Ni(cod)$_2$ (COD = cycloocta-1,5-diene) produced a deep red solution, from which complex 2 was isolated as an orange solid in 67% yield (Scheme 1). The $^1$H NMR spectrum of 2 revealed a C$_2$ symmetry, instead of C$_3$, expected for a Ni-NHC complex. A resonance corresponding to the N$_2$CH proton appeared at 5.82 ppm, substantially high-field shifted from 8.84 ppm in 1. The crystal structure confirmed the distorted tetrahedral geometry of the N$_2$CH carbon on the NCN pincer complex, with the sum of the bond angles formed by the heavier elements at C1 measuring 332.5° (Figure 1). With 1.848(5) Å, the C1-Ni1 bond is short when compared to similar bonds in nickel(II) pincer complexes featuring dialkylmethyl or diarylmethyl central platforms (av. Ni-C 1.98(2) and 1.986(3) Å, respectively). Although the preference for alky vs. carbene coordination is common for complexes of dialkyl and diaryl carbenedes, it is very rare for complexes of the more stable NHMCs. Only few such examples have been structurally characterized to date, and we propose that the competitive delocalization of the nitrogen lone pairs onto the exocyclic amide moieties is responsible for a reduced stabilization of the carbene structure. In support of this theory, the two C-N bonds of each pendant amide group in 2 are almost equal in length. Treatment with potassium hexamethyldisilazide in toluene yielded nevertheless the NHC complex 3, with nickel retaining the chlorine in its coordination sphere. The $^1$H NMR spectrum of this Ni$^0$ complex confirmed the disappearance of the resonance corresponding to the N$_2$CH proton.

A crystal structure of 3 revealed a dimeric arrangement with two anionic NiNCl moieties bridged by the potassium counterions (Figure 2). In turn, the π-coordination of the Dipp groups completes the distorted square planar coordination geometry of the potassium ions. The carbene carbon C1 is close to planarity, with a sum of bond angles of 350.8°. At 1.795(7) Å, the Ni1-C1 bond in 3 is shorter than in 2, and in fact shorter than all reported Ni$^0$N$_2$C bonds (1.827(6) to 2.021(4) Å, av. 1.91(4) Å). The conversion to an NHC is accompanied by the expected shortening of the C-N bonds to the carbene carbon, from 1.44 Å in the toluene-$d_4$ and 1.355(10), Cl1-K1 2.948(3), Cl1-K1’ 2.977(3), Ni2-C 1-N3 117.3(4), C1-Ni1-Cl1 175.0(2), N3-Ni1-N4 159.2(2).

Complex 3 was expected to be prone to oxidative addition reactions upon elimination of KCl. Exposure to ammonia gas at room temperature in either toluene or THF yielded immediately a dark solution. $^1$H NMR spectroscopy indicated the presence of two compounds, one with C$_{2v}$ and the other with C$_3$ symmetry, which were assigned to 4 and 5, respectively. For the former compound, the $^1$H NMR spectrum of the mixture displayed the two expected doublet resonances corresponding to the diastereotopic methyl groups of the ligand, and a resonance corresponding to the coordinated ammonia at -0.11 ppm in toluene-$d_4$ and 0.45 in THF-$d_8$. For the activation product 5, the spectrum displayed four doublet resonances corresponding to the methyl groups of the ligand, and a resonance for the amide protons at -2.97 ppm in toluene-$d_4$ and -3.63 ppm in THF-$d_8$. Additionally, the signal corresponding to the N$_2$CH proton was observed at 5.13 ppm in toluene-$d_4$ and 5.22 ppm in THF-$d_8$. The two structural isomers were present in 4:5 ratios of ca. 4:1 in toluene-$d_4$ and 2:3 in THF-$d_8$, with intermediate ratios in mixed-solvent systems, indicating that an equilibrium was present in solution (Figure 3). This was further confirmed by

EXSY NMR spectroscopy, which showed cross-peaks between the signals corresponding to the NH\textsubscript{2} protons in 4 and the NH\textsubscript{2} and N\textsubscript{2}CH protons in 5 (see Supporting Information). Exposure of a solution of 4 and 5 in toluene-d\textsubscript{6} to ND\textsubscript{3} resulted, as expected, in the rapid decrease of the intensity of the 1\textsuperscript{H} NMR signals corresponding to the N\textsubscript{2}CH, NH\textsubscript{2} and NH\textsubscript{2} protons following the exchange with deuterium. Solvent removal from solutions containing 4 and 5 produced a highly sensitive microcrystalline dark green solid that could be stored for weeks at -38 °C in the absence of air and moisture. Its identity could not be confirmed due to the insufficient quality of the single crystals. No distinctive IR bands corresponding to N-H vibrations were observed. The solid redissolved in THF and toluene giving solutions that displayed properties identical to those observed for the solution of in-situ prepared 4/5.

Density functional theory calculations were performed on model compounds 4\textsuperscript{th} and 5\textsuperscript{th} in which the Dipp substituents were replaced by phenyl groups. The gas phase free energies of the optimized structures show that 4\textsuperscript{th} is favored over 5\textsuperscript{th} by 6 kJ\textsuperscript{-1}mol\textsuperscript{-1} in low dielectric media, in good agreement with the value of 3.4 kJ\textsuperscript{-1}mol\textsuperscript{-1} derived from the relative concentrations in toluene-d\textsubscript{6} solutions. When a continuum solvent model for THF was used, the calculations predicted 5\textsuperscript{th} to be lower in energy than 4\textsuperscript{th} by 21 kJ\textsuperscript{-1}mol\textsuperscript{-1}. This matches less well the experimentally derived value of 1.0 kJ\textsuperscript{-1}mol\textsuperscript{-1}, but it shows the same preference for 5\textsuperscript{th}.

The 4 - 5 system represents the first instance where the thermodynamic stability of the two complexes is comparable, allowing for the observation of both species in solution.

In conclusion, we report here a highly active Ni\textsuperscript{0} pincer complex that is able to reversibly activate ammonia at room temperature in a ligand-assisted process. Both coordinated (ammine, 4) and activated (amide, 5) coexist in solution in comparable, solvent-dependent proportions. The unprecedented ability of the six-membered NHC in 3 to assist N-H bond activation, accepting the proton at the carbene carbon, opens up a new page in the chemistry of this versatile family of compounds that have found widespread applications as ancillary ligands.
