Shape Coexistence in the Neutron-Deficient Even-Even $^{182-188}$Hg Isotopes Studied via Coulomb Excitation

Isotopes Studied

$^{182}$Hg, $^{184}$Hg. The results show that the ground state is slightly deformed and of oblate nature, while a larger deformation for the excited states was noted in $^{188}$Hg.

Coulomb-excitation experiments to study electromagnetic properties of radioactive even-even Hg isotopes were performed with 2.85 MeV/nucleon mercury beams from REX-ISOLDE. Magnitudes and relative signs of the reduced $E2$ matrix elements that couple the ground state and low-lying excited states in $^{182-188}$Hg were extracted. Information on the deformation of the ground and the first excited states was deduced using the quadrupole sum rules approach. Results show that the ground state is slightly deformed and of oblate nature, while a larger deformation for the excited state was noted in $^{182}$Hg. The results are compared to beyond mean field and interacting-boson based models and interpreted within a two-state mixing model. Partial agreement with the model calculations was obtained. The presence of two different structures in the light even-mass mercury isotopes that coexist at low excitation energy is firmly established.

Shape coexistence, whereby at low energy near-degenerate states characterized by different shapes appear, is an intriguing phenomenon that occurs in various mesoscopic systems. However, the distinctive character of shape coexistence in atomic nuclei lies in the subtle interplay between two opposing trends [1]. Shell and subshell closures invoke a stabilizing effect leading to sphericity while residual interactions between protons and neutrons outside closed shells drive the nucleus to deformation. Understanding the manifestation of shape coexistence could be the key to reveal the microscopic origin of collectivity and the apparent evaporation of the shell structure in atomic nuclei. In the region around the light lead isotopes, with proton number $Z=82$, a substantial amount of information has been collected using a wide spectrum of experimental probes such as decay studies, optical spectroscopy studies, and in-beam spectroscopy investigations [1,2]. This resulted, amongst other things, in the observation of strong staggering in the isotope shifts in the mercury isotopes [3], the discovery of triple shape coexistence in $^{186}$Pb [4], and an early onset of deformation in the light polonium and platinum isotopes as evidenced through laser spectroscopy (see, e.g., [5]). The global trends of these experimental findings are reproduced by theoretical descriptions, such as phenomenological shape-mixing calculations and contemporary symmetry-guided models (e.g., [6,7]), and beyond mean-field approaches [5,8,9]. However, there is a lack of direct experimental information on the nature of the quadrupole deformation or on the mixing of the states belonging to the coexisting structures.

The energy-level systematics of the even-even mercury isotopes ranging from $A=190$ to $A=198$ exhibit a nearly constant behavior of the energy of the yrast states [2,10]. Mean-field calculations suggested that these states are related to a weakly deformed oblate ground state [1,8,9]. For the lighter, neutron-deficient mercury isotopes ($A \leq 186$), this pattern is distorted through the appearance of more deformed states, interpreted to be prolate, which decrease in excitation energy, reaching a minimum around the neutron midshell ($N=104$, $^{184}$Hg), and mix with the weakly deformed states. However, as shown by the mean-square charge radius measurements [11], it appears that mixing in the ground states is small (see, e.g., [5]).

In spite of this distortion, the energy of the $2^+_1 \rightarrow 0^+_1$ state of even-even Hg isotopes around the $N=104$ midshell is relatively constant. Moreover, recent lifetime measurements for the yrast states reveal comparable values of the reduced transition probabilities, $B(E2; 2^+_1 \rightarrow 0^+_1)$, for even-even $^{182-188}$Hg isotopes [12–14]. On the other hand, strong conversion of $2^+_1 \rightarrow 2^+_1$ transitions associated with an $E0$ component have been observed [15,16], indicating mixing of these states. In order to resolve these apparently contradictory observations and to obtain information on the mixing and the type of deformation, the electromagnetic properties of low-lying yrast and non-yrast states in $^{182-188}$Hg have to be determined. While Coulomb excitation is the preferred probe, energetic radioactive beams are required in this case.

Coulomb excitation of even-even $^{182-188}$Hg was carried out at the REX-ISOLDE facility at CERN [17,18]. A radioactive mercury-ion beam was accelerated to an energy of 2.85 MeV/nucleon and delivered to the MINIBALL setup [19]. Coulomb excitation of $^{182-188}$Hg was induced by $^{120}$Sn, $^{107}$Ag, and $^{112,114}$Cd targets of thicknesses of 2.3, 1.1, and 2 mg/cm$^2$, respectively. The beam intensity varied between $3.5 \times 10^3$ pps up to 0.2–2.0 $\times 10^5$ pps for $^{182}$Hg and $^{184-188}$Hg, respectively. The experimental setup consisted of the MINIBALL $\gamma$-ray spectrometer coupled with the double-sided silicon strip detector (DSSD) [19,20].

The low-energy states in $^{182-188}$Hg that were populated in the experiment are presented in Fig. 1. A random-subtracted, $\gamma$-ray spectrum of a $^{185}$Hg beam incident on a $^{112}$Cd target, in coincidence with both projectile and target particles and Doppler corrected for a projectile, is presented in Fig. 2. The population of the $2^+_1$, $2^+_2$, and $4^+_1$ states in $^{182}$Hg can be clearly observed. Moreover, intense $K$-x-ray peaks are present in the spectrum. A careful analysis of these peaks, that were Doppler broadened, reveals that they stem partly from x rays produced in atomic process when the $^{184}$Hg ions pass the target and partly from electron conversion accompanying the observed $\gamma$-ray transitions.

![FIG. 1 (color online). Low-energy part of the level schemes, relevant to the Coulomb-excitation analysis, of the even-even $^{182-188}$Hg isotopes. Level and $\gamma$-ray transition energies are given in keV. Widths of the arrows are proportional to the observed $\gamma$-ray yields normalized to the $2^+_1 \rightarrow 0^+_1$ transition. The intensity of the $2^+_2 \rightarrow 2^+_1$ transition in $^{182}$Hg, not visible in the spectrum in Fig. 2 due to the presence of Compton edge of $2^+_1 \rightarrow 0^+_1$ transition, was deduced from the $\gamma - \gamma$ ray spectrum gated on the $2^+_1 \rightarrow 0^+_1$ peak. Mixing amplitudes squared of the unperturbed structure (I), $\alpha_I^2$, are taken from [14].](162701-2)
and the deexcitation of the $0_1^+$ state to the ground state [21].
From their intensities, the population of the $0_1^+$ excited state was deduced and information on all connecting $E2$ matrix elements ($ME2$'s) was obtained, albeit with limited precision. Data of similar quality were collected for $^{184,186,188}$Hg. Crucial for this analysis was the knowledge of the conversion coefficient of the $2^+_1 \rightarrow 2^+_1$ transition, as it contained a large $E0$ component. The total conversion coefficient, $\alpha(2^+_1 \rightarrow 2^+_1)$, deduced from the $\beta$-decay of $^{182,184}$TI, is equal to 4.7 ± 1.3 in $^{182}$Hg and 23 ± 5 in $^{184}$Hg [15].
In order to determine $ME2$'s in $^{182-188}$Hg, the Coulomb-excitation least-squares fitting code GOSIA [22] was used. The code fits a set of reduced matrix elements to reproduce the measured yield of $\gamma$-ray transitions populating the Coulomb-excited states of $^{182-188}$Hg, taking into account known spectroscopic data related to electromagnetic matrix elements: branching ratios [15,23,24], conversion coefficients [15,25], and lifetimes of the yrast and non-yrast states [13,14,26]. Importantly, for all cases, the fitted $B(E2; 2^+_1 \rightarrow 0^+_1)$ values obtained without lifetimes as additional data are consistent with results reported in Refs. [12–14].

The analysis of the Coulomb-excitation data brings information on the relative signs of transition $ME2$'s. The absolute sign of a single, transition $ME2$ has no physical meaning, since it depends on the arbitrary choice of the relative phases of a wave function of initial and final states. However, the sign of the interference term, e.g., the sign of the interference term, e.g., $\langle 0^+_1 \mid E2 \mid 2^+_0 \rangle / \sqrt{\langle 0^+_1 \mid E2 \mid 2^+_0 \rangle \langle 2^+_0 \mid E2 \mid 0^+_1 \rangle}$, is independent of the chosen convention and can be determined experimentally since it influences the Coulomb-excitation cross section.

The extracted $ME2$'s are shown in Table I. These results can be analyzed in terms of the quadrupole deformation parameters, $Q$ and $\delta$, which are universal variables of quadrupole collective models within the General Bohr Hamiltonian (GBH) [27]. Using the quadrupole sum rules approach [28–31] the quadrupole invariants, $(Q^2)$ and $(Q^3 \cos(3\delta))$, can then be obtained. Invariants describe the charge distribution of a nucleus in a given nuclear state. The sum of products of the relevant $ME2$'s between $0^+$ and $2^+$ states given in Table I are shown in Fig. 3: the sum of squared $E2$ matrix elements (SSM) related to $\langle Q^2 \rangle$ and the sum of triple products of $E2$ matrix elements (STM) related to $\langle Q^3 \cos(3\delta) \rangle$. The quadrupole invariants can be further related to the GBH collective model variables [31], $\beta$ (overall deformation parameter) and $\gamma$ (nonaxiality parameter). It can be concluded that the ground states of the even-even mercury isotopes are weakly deformed with a $\beta$ value close to 0.15 and are consistent with an oblatelike deformation $[(\cos(3\delta)) = -1]$, while the excited $0^+$ states are more deformed. The lack of precision on key matrix elements, especially in $^{186,188}$Hg, prevents us from drawing firm conclusions on the nature of the deformation of the ground ($^{186}$Hg) or excited ($^{186,188}$Hg) $0^+$ states.

Table I. Reduced transitional and diagonal $E2$ matrix elements between low-lying states in $^{182-188}$Hg obtained in this work. The error bars correspond to $1\sigma$. The $(\pm)$ indicates that the sign of the $\langle 0^+_1 \mid E2 \mid 2^+_0 \rangle$ for $^{186}$Hg was not determined.

The BMF excitation spectrum of neutron-deficient Hg isotopes is dominated by two coexisting rotational bands.
with very different moments of inertia. In the BMF calculation, when going to the lighter masses, these two bands cross, in contradiction with experiment. Down to \( N = 106 \), the BMF Hg ground states are predicted to be predominantly oblate and the first excited 0\(^+\) state to be prolate, whereas for 100 \( \leq N \leq 104 \), the ground state is predominantly prolate and the 1\(^+\) state is an almost equal mixture of prolate and oblate configurations [9]. The sums of products of the relevant ME\(^2\)'s from the BMF calculations, SSM and STM, take values that reflect this behavior. As can be seen in the left part of Fig. 3 the SSM sum for the 0\(^+\) ground states deduced from BMF ME\(^2\)'s values agree with data for \( A = 186 \) and 188. By contrast, for \( A = 182 \) and 184, the BMF SSM values for the ground state and the second 0\(^+\) are inverted with respect to experiment. This disagreement is also visible in the STM values plotted in the right panel of Fig. 3.

In the IBM approach [32], whereby particle-hole pair excitations across the \( Z = 82 \) closed shell are explicitly included (for a similar calculation see, e.g., [6,33]), agreement between experiment and calculations for the SSM sum is noticed. However, as in the case of the BMF calculations, only partial agreement between experiment and theory is observed for the sum of triple product of IBM ME\(^2\)'s. The disagreements for the two models are not understood and point to missing ingredients in the calculations. This is further addressed in [32].

The assumption that the excited states of the mercury isotopes can be described by two distinct configurations can also be tested by comparing our results with those from a two-state mixing model. Within this simple, phenomenological approach, following the notation given in Refs. [34,35], the observed physical states can be written as linear combinations of two unmixed structures—structure I and structure II—with specific mixing amplitudes.

The experimental (mixed) ME\(^2\)'s can be expressed in terms of the pure intraband matrix elements which couple unperturbed states and of the mixing amplitudes. It is assumed that there are no interband unperturbed transitions between the two pure structures. The mixing probabilities, taken from Ref. [14] and reproduced in Fig. 1, were derived from the fit of known, higher-lying level energies of rotational bands, built upon the first two 0\(^+\) states, using the variable moment of inertia (VMI) model [36].

All matrix elements within the unperturbed bands (ME\(^2\)'s between 0\(^+\) and 2\(^+\) as well as spectroscopic moments of the 2\(^+\)'s) were fitted as a common set for \(^{182,184,186,188}\)Hg to optimally reproduce experimental results. This yields 1.2 and 3.3 eb values for the \( \langle 0^+_I \| E2 \| 2^+_I \rangle \) and \( \langle 0^+_II \| E2 \| 2^+_II \rangle \), respectively, while the diagonal matrix elements for the 2\(^+_I\) and 2\(^+_II\) states result in 1.8 and −4.0 eb, respectively. To derive mixed ME\(^2\)'s connecting 4\(^+\) and 2\(^+\) states, the unperturbed \( \langle 2^+_I\| E2 \| 4^+_I\rangle \) matrix elements were extrapolated from the \( \langle 0^+_I\| E2 \| 2^+_I\rangle \) values using the rotational formula [37] and are equal to 1.9 and 5.3 eb, respectively. Figure 4 shows a comparison between the experimental transition ME\(^2\)'s and those resulting from the two-state mixing model.

Most of the experimental results are well reproduced within the two-state mixing model supporting the interpretation of two unperturbed sets of states that mix when states with equal spin and parity are close in energy. Reduced transition probabilities between 2\(^+\) and 0\(^+\) states, extracted in this work, belonging to two pure structures are significantly different [the \( B(E2; 2^+_I \rightarrow 0^+_I) \) value is 7.5 times larger than the \( B(E2; 2^+_II \rightarrow 0^+_II) \)] hinting towards different magnitudes of quadrupole collectivity, consistent with the conclusions discussed above (Fig. 3). Moreover, within the collective models (e.g., Bohr-Mottelson model [37]) when two bands are described by the same \( K \) quantum number, an opposite sign of the diagonal matrix elements of the 2\(^+_I\) and 2\(^+_II\) states indicates a change in the type of deformation for the two configurations—less deformed and of oblate nature (structure I) and more deformed and of prolate nature (structure II).

The near-constant excitation energy of the 2\(^+_I\) state and of the \( \langle 0^+_I \| E2 \| 2^+_I \rangle \) value can now be explained within the two-state mixing model in spite of a substantial change in the mixing amplitude \( a_{j=2} \). The 2\(^+_I\) states change from a rather pure component of structure I (for \(^{180}\)Hg) into a state with a dominant component of structure II in \(^{182}\)Hg. The small mixing in the 0\(^+\) ground states compensates for this effect as can be observed from the \( \langle 2^+_I \| E2 \| 0^+_I \rangle \) (see Fig. 4).

The predictions of the two-level mixing model deviate partially from the experimental results obtained for \(^{184}\)Hg, where approximately 50% of mixing between 2\(^+_I\) and 2\(^+_II\) states was deduced [14]. While the absolute values of most matrix elements are in reasonable agreement, the signs are not. The influence of variations of the mixing amplitudes within 20% has been investigated, but did not cure this discrepancy.

In conclusion, the electromagnetic properties of low-lying states of light, even-mass neutron-deficient \(^{182–188}\)Hg
were studied through Coulomb excitation using postaccelerated radioactive-ion beams. Combining these experimental data with results from $\beta$-decay studies of $^{182,184}$Tl [15] and lifetime measurements [12–14,26] yielded a unique set of ME2’s between yrast and non-yrast $0^+$, $2^+$, and $4^+$ states including their relative signs. This enabled us to use the quadrupole sum rules to analyze the quadrupole collectivity of the ground and excited $0^+$ states of $^{182–188}$Hg. It shows that the ground states of mercury isotopes are weakly deformed and of predominantly oblate nature, while the excited $0^+$ states of $^{182,184}$Hg are more deformed. Comparison of sums of squared MME data with results from theoretical predictions and partial agreement with BMF predictions.

Properties of the lowest-lying states of $^{182–188}$Hg were interpreted within a two-state mixing model. It was shown that the magnitudes of most of the experimentally determined transition ME2’s can be explained in terms of mixing of two significantly different configurations. The unmixed matrix elements extrapolated from our data, using the VMI model, towards higher-lying states, where no mixing occurs, are in a fair agreement with the theoretical predictions and lifetime measurements [12,14]. These findings support the underlying assumption of two different structures that are pure at higher spin values and mix at low excitation energy. For these light mercury isotopes, the new data imply significant changes in the composition of the $2^+_1$ states via large variations in the deduced mixing amplitudes. This refutes the common interpretation according to which states, in an isotopic chain, of comparable energy and similar transition strength always manifest a similar structure.

The authors would like to thank the ISOLDE facility for providing excellent beams. This work was supported by the FWO-Vlaanderen (Belgium), an FWO Pegasus Marie Curie Fellowship (L. P. G.), by GOA/2010/010 (BOF KULeuven), by the IAP Belgian Science Policy (BriX network P6/23 and P7/12), by the European Commission within the 7th Framework Programme through I3-ENSAR (Contract No. RI3-CT-2010-262010), by the U.K. Science and Technology Facilities Council, by the German BMBF under Contracts No. 06DA9036I, No. 05P12RDCIA, No. 06KY205I, No. 05P09PKC15, No. 05P12PKFNE, No. 05P12WOFNF, and No. 09MT9156, Academy of Finland (Contract No. 131665), by the Spanish MINECO through FPA2010-17142 project and the Spanish Project No. FIS2011-28738-C02-02.
