The 28 GHz Ion Source VENUS (versatile ECR for nuclear science) is back in operation after the superconducting sextupole leads were repaired and a fourth cryocooler was added. VENUS serves as an R&D device to explore the limits of electron cyclotron resonance source performance at 28 GHz with its 10 kW gyrotron and optimum magnetic fields and as an ion source to increase the capabilities of the 88-Inch Cyclotron both for nuclear physics research and applications. The development and testing of ovens and sputtering techniques cover a wide range of applications. Recent experiments on bismuth demonstrated stable operation at 300 e\textmu A of Bi\textsuperscript{31+}, which is in the intensity range of interest for high performance heavy-ion drivers such as FRIB (Facility for Rare Isotope Beams). In addition, the space radiation effects testing program at the cyclotron relies on the production of a cocktail beam with many species produced simultaneously in the ion source and this can be done with a combination of gases, sputter probes, and an oven. These capabilities are being developed with VENUS by adding a low temperature oven, sputter probes, as well as studying the RF coupling into the source.

I. VENUS ECR ION SOURCE

The VENUS (versatile ECR for nuclear science) electron cyclotron resonance (ECR) ion source, shown in Fig. 1, is a fully superconducting ion source. The three solenoids and the sextupole coils are made out of Niobium-Titanium alloy embedded in a Copper matrix. VENUS is both an operating ion source for Lawrence Berkeley National Lab’s 88-Inch Cyclotron as well as prototype for FRIB. The source has been an invaluable tool in expanding the limits of ECR ion sources, in exploring the scaling laws formulated by Geller,\textsuperscript{1} and provides a starting point for the development of a 4th Generation ECR ion source.\textsuperscript{2} Its operating parameters are listed in Table I.

Last year 75\% of the total beams delivered to the 88-Inch Cyclotron facility’s users came from the 14 GHz AECR-U ion source. These beams include cocktails\textsuperscript{3} and high intensity metal ion beams. Since VENUS’ first re-commissioning beam on July 2010, after the repair of one of the sextupole leads,\textsuperscript{3} one goal has been to integrate the VENUS ECR ion source into regular operation in order to provide relief and serve as a back up to the AECR-U ion source. This includes the fabrication of a low temperature oven, which will be discussed below, the development of a multi-metal sputter probe, currently under way, and the development of a high temperature oven capable of reaching 2300 °C, also discussed below. The low temperature and high temperature ovens are needed to produce high intensity ion beams for the 88-Inch Cyclotron’s Heavy Element research. The low temperature oven can also be used to produce \(^{209}\text{Bi}^{41+}\), which is needed in the 4.5 MeV/nucleon cocktail.

II. HIGH TEMPERATURE OVEN

The VENUS high temperature oven is installed axially as shown in Fig. 2. It is intended to be run up to 2300 °C by resistive heating. The combination of high DC oven current, needed to reach 2000 °C, and the strong 4T magnetic field at the VENUS injection end exerts a transverse force on the oven causing undesirable movement of the oven components.\textsuperscript{5}

A test of the oven in the source at 254 A, 407 W of total power, and a 3.4 T injection field resulted in a failure of the Tungsten crucible. The water cooled copper oven leads that carry the current to the oven become soft and bend, as shown in Figs. 3(a) and 3(b), shearing off the refractory metal oven stem which sits in the copper housing.

The oven was tested in a test stand while monitoring the temperature of the copper leads, at the position shown with a star in Fig. 3(a). This confirmed there was insufficient cooling. As shown in Fig. 4, even at 300 W power, the copper leads’ temperature exceeded 100 °C indicating the onset of boiling water and loss of efficient heat transfer. The power needed to reach 2000 °C is ∼1100 W.

A modification was made to the Cu leads, as shown in Fig. 3(c), to provide a larger surface area of Cu for heat transfer. The results in Fig. 4 show a significant improvement in the lead cooling. At a power of 1100 W the Cu leads only reached 80 °C. The high temperature oven then was retested in the VENUS ion source to produce a \(^{48}\text{Ti}\) beam. The oven was run up to 315 A, 565 W in a 3.4 T injection magnetic field successfully. Figures 3(c) and 3(d) show that the oven after testing did not bend. The oven was run for three con-
secutive days at an average output of 75 eμA of $^{48}\text{Ti}^{14+}$. Figure 5 shows a spectrum taken while running $^{48}\text{Ti}$. The total consumption rate was 2.9 mg/h.

III. LOW TEMPERATURE OVEN

The VENUS low temperature oven, shown in Fig. 6, is designed to reach temperatures no higher than 650 °C. Using a Dalton Watt-Flex Cartridge Heater, the copper oven housing the material is heated while simultaneously monitoring the temperature with a thermocouple. The low temperature oven is inserted axially, in place of the high temperature oven, shown in Fig. 2, and its support assembly is water cooled.

The low temperature oven was tested successfully in the VENUS ion source using $^{40}\text{Ca}$. Figure 7 shows a spectrum taken while running $^{40}\text{Ca}$ and producing 400 eμA of $^{40}\text{Ca}^{11+}$. This is an important result for us since Ca is a highly coveted beam by the Berkeley Gas-filled Separator group, who request 2 pμA of beam current on target. Work is being done to maximize the transport from the ion sources to the experimenter. The total consumption rate for the oven was 4 mg/h.

IV. RECENT BEAM INTENSITIES

Shortly after its re-commissioning in July 2010 VENUS was already showing promising results. Table II, which

V. RF COUPLING

The VENUS RF coupling system has both 18 GHz and 28 GHz waveguide antennas, which are used to inject RF power and shown in Fig. 8. The 18 GHz antenna was recently modified with a 141 mm extension terminated with a 30° bevel. This modification reduced the CW reflection coefficient measured with plasma in the chamber from about 8% to about 1% and it directs to first pass RF power from the antenna onto the plasma chamber axis at the location of the ECR zone to improve the absorption of power.

The 18 GHz 2.0 kW klystron amplifier can be pulsed to make transient measurements. For these experiments the VENUS waveguide systems were reconfigured to measure cross coupling of 18 and 28 GHz with diode detectors as

shown in Fig. 9 and a pulser was added to the 18 GHz amplifier chain. This made it possible to measure the time response of the reflected 18 GHz power in coincidence with the 18 GHz power transmitted out through the 28 GHz waveguide. It was also possible to measure the 28 GHz power transmitted out through the 18 GHz waveguide, but the gyrotron power can only be ramped slowly, which does not make it possible to pulse the power at 28 GHz.

An extensive set of measurements was done on VENUS using the microwave configuration described above. It is beyond the scope of this paper to describe all of the results, rather one data set, which shows some of the interesting phenomena observed, will be discussed here. In Figs. 10(a) and 10(b) the transient responses of the reflected and transmitted power are shown for a 340 W 18 GHz pulse. The RF is switched off for 2.5 s to extinguish the plasma from the previous pulse and then at \( t = 0 \) it is switched on for 2.5 s. At turn on, RF fields rise rapidly and reach initial equilibrium in a few \( \mu \)s as shown by the rapid rise of the transmitted power. During the first 0.6 ms the plasma chamber has no discernable plasma absorption and it acts as an over-coupled, over-moded high Q cavity. At 0.6 ms, the plasma begins to affect the RF fields and the transmitted power begins to oscillate and decay. At 1.12 ms, the transmitted power goes to almost zero, indicating that the RF fields have collapsed due to the build up of plasma density and its associated loading. After a few more oscillations in the reflected and transmitted power, the transmitted power drops again to very low levels, indicating the RF fields are now quite low. Over a longer time period shown in Fig. 10(b), the reflected and the transmitted power rise slowly and then saturate after about 200 ms.

When the transmitted power drops to low levels, the injected 18 GHz is being strongly absorbed by the plasma and the RF fields are probably best understood as near field power from the antenna being strongly absorbed in the first pass. Here, the plasma chamber walls play a secondary role. The reflected signal remains greater than 0 at all times during these transients and at \( t > 1.5 \) ms the reflection coefficient \( (Pr/Pi) \) is only about 1%–2% which is typical of the reflection coefficient for the beveled antenna in free space.

The transient transmission measurements show that the buildup of very high RF fields before the plasma loading occurs is an important part of the preglow dynamics. Likewise, the strong absorption that follows, especially at about 1.5 ms, where the transmitted signal is roughly only 4% of its initial value at turn on, indicates that the RF field levels are reduced about 1/5 their initial values. The long slow rise of the transmitted power shown in Fig. 10(b) indicates a small increase in the RF field strength, but why the time constant for this rise is so long is unclear at this stage.

The very strong absorption of RF power in the CW situation by the plasma indicates that it is unrealistic to model this as coupling to a high Q cavity with distinct cavity modes. This is especially important in understanding RF coupling in over-moded cavities where the diameter to free space wavelength is greater than 4. In this case, it is more appropriate to discuss the rf coupling to the plasma as single pass and multi-pass adsorption of injected waves rather than as an ensemble of cavity modes. Here, the near field pattern of the injection waveguide will be critical in determining the RF coupling.

Unlike the 18 GHz injected in \( \text{TE}_{11} \) mode, the present 28 GHz injection in VENUS uses a 35 mm diameter round waveguide in the \( \text{TE}_{01} \) mode shown in Fig. 8. The \( \text{TE}_{01} \) mode has a hollow RF power distribution with no RF power on axis, a maximum power density at 48% of waveguide radius and zero power at full radius. While this mode is ideal for low loss in the transmission line between the gyrotron and VENUS, it does not appear to be the best choice for coupling to the ECRIS plasma. In many plasma fusion devices, waveguide components are used to transform RF power from \( \text{TE}_{01} \) mode to either a \( \text{TE}_{11} \) or \( \text{HE}_{11} \) mode before directing it onto the ECR location. Analysis of how to modify the injection geometry of the VENUS 28 GHz system to adopt this technique is now underway. Two methods are being considered. The first would convert the incoming 28 GHz \( \text{TE}_{01} \) mode to a \( \text{HE}_{11} \) mode using waveguide components as was done on the Wisconsin HSX Stellerator. The second more complex method would be to convert the 28 GHz into a quasi-Gaussian beam and use mirrors to direct the power. In any case,
improving the coupling of the 28 GHz to the plasma in VENUS has the potential to significantly improve its performance, since qualitatively the 18 GHz RF injected in the TE11 mode appears to couple more efficiently than the 28 GHz RF injected in the TE01 mode.

VI. FUTURE WORK

The performance of VENUS continues to improve and work is ongoing to expand its range of capabilities. Near term plans include the development of high intensity uranium beams and high efficiency $^{48}$Ca beams, as well as a modification to improve the coupling of the 28 GHz to the plasma.
