Abstract

The new Decay Total Absorption Spectrometer (DTAS) has been commissioned with low energy radioactive beams at the upgraded IGISOL IV facility. The DTAS is a segmented detector composed of up to 18 NaI(Tl) crystals and it will be a key instrument in the DESPEC experiment at FAIR. In this document we report on the experimental setup and the first measurements performed with DTAS at IGISOL. The detector was characterized by means of MC simulations, and this allowed us to calculate the response function of the spectrometer and analyse the first cases of interest.

Keywords: β decay, total absorption γ-ray spectrometer, exotic nuclei, ISOL facilities, β-delayed neutron emitters

1. Introduction

In Nuclear Physics, the β-strength distribution can be used to study nuclear structure since it is sensitive to the overlap of the initial and final wave functions of the parent and daughter states. The relation of the β-intensity $I_β$ to a state of energy $E_x$ with the β-strength $S_β$ and the squared theoretical matrix elements $B$ is given by:

$$
S_β(E_x) = \frac{I_β(E_x)}{f(Q_β - E_x)T_{1/2}} = \frac{1}{C} B(E_x) \tag{1}
$$

where $T_{1/2}$ is the half life of the parent nucleus, $f(Q_β - E_x)$ is the statistical Fermi function and $C$ is a constant.

Total absorption γ-ray spectroscopy (TAGS) has been shown to be an effective tool to determine β-decay intensity distributions for nuclei far from the valley of β stability \[1,2,3\]. In contrast with high resolution spectroscopy, where HPGe detectors are used to detect individual γ rays, TAGS aims to detect the full β-delayed electromagnetic cascade, avoiding the systematic error known as the Pandemonium effect \[4\] related to the modest efficiency of the HPGe detectors, that shifts the apparent $I_β$ distribution to lower excitation energies. The main
requirement for such a detector is to maximize the efficiency by using large scintillator crystals to cover a solid angle of $\sim 4\pi$. For an ideal detector, with 100% $\gamma$-ray efficiency, the measured energy spectrum would provide directly the $\beta$-intensity distribution convoluted with the instrumental resolution. Bearing this in mind a new spectrometer has been designed and constructed [5] for the study of exotic nuclear species at the focal plane of the FAIR-NUSTAR Super Fragment Separator in the DE-SPEC experiment [6]. Such a system will provide information relevant to studies of nuclear structure and nuclear astrophysics.

The Decay Total Absorption $\gamma$-Ray Spectrometer (DTAS) consists of a maximum of 18 rectangular NaI(Tl) crystals with dimensions $150 \text{ mm} \times 150 \text{ mm} \times 250 \text{ mm}$. In the configuration foreseen for FAIR [5], a sixteen-module assembly will be coupled to the Advanced Implantation Detector Array (AIDA) [7]. In the present work, however, the full eighteen-module assembly, depicted in Figure 1, has been used allowing us to place the beam pipe and a HPGe ancillary detector inside. This configuration exhibits a 65% photopeak efficiency at 1 MeV.

2. Experiment

2.1. Motivation

The experiment focused on the study of uranium fission fragments with the TAGS technique. Most of these nuclei have large $Q_{\beta}$ values, and are suspected to suffer from the Pandemonium effect. Many of them are involved in reactor decay heat summation calculations [14] and are important contributors to the antineutrino spectra from reactors [8]. There are also a few cases of interest in relation to $\beta$-delayed neutron emission, in which the neutron separation energy $S_{\text{n}}$ in the daughter nucleus is lower than the decay energy window $Q_{\beta}$, and competition between $\gamma$ and neutron emission from neutron unbound states can be studied [9][10].

2.2. Experimental setup

The first experiment with DTAS was performed at the upgraded IGISOL IV facility of the University of Jyväskylä, Finland [11] in February 2014. Proton beams from the MCC30 cyclotron were used to induce fission in a natural Uranium target. At IGISOL the fission products recoil out of the target and stop in a gas (usually helium). Then, a jet gas flow transports them through a differential pumping system directly into the first stage of the mass separator.

One advantage of the IGISOL facility is the possibility to use the JYFLTRAP double Penning trap to separate out isobaric contaminants [12]. In our experiment, after the purification in JYFLTRAP the activity was implanted on a tape placed in vacuum at the centre of DTAS. The tape transport system runs in cycles which were optimised for each nucleus. The DTAS was surrounded by shielding composed of stainless steel sheets, lead bricks and aluminium, which served to reduce the background counting rate by one order-of-magnitude. The whole assembly, detector plus shielding, laid on an aluminum table with two rails that enable to separate the DTAS in two independent structures, each of them containing half of the crystals. The full experimental arrangement is shown in Figure 2.

![Figure 2: Setup at IGISOL with the DTAS surrounded by the shielding. The beam pipe enters from the left side and the HPGe detector from the right side (see Figure 1 right).](image)

Both anode and last dynode signals from each phototube were shaped with Mesytec MSI-8p
preamplifiers. Anode signals were added to provide a timing signal using a constant fraction discriminator. Dynode signals were further processed with Mesytec MSCF-16 shapers before being sent to the ADC to reconstruct the total absorption spectrum. Data were collected simultaneously in a conventional triggered acquisition system and in a new trigger-less system. Each individual spectrum covered a range of 15 MeV with a threshold of ∼ 80 keV.

A method to correct changes in the photomultiplier gain has been developed based on an external reference detector. This was a 3” × 3” well-type NaI(Tl) crystal with a weak 137Cs source inside. This detector and all DTAS modules were illuminated with a 6010 BNC 490 nm light pulser source through a bundle of borosilicate glass fibers. The reference detector was employed to monitor the light source thus allowing a gain correction in all phototubes. This was essential to avoid distortions in the spectra and we achieved an energy resolution of 8.8% at 662 keV.

In order to eliminate background events in the spectrometer, coincidences with β particles were required. A 3 mm plastic scintillator detector with 30% detection efficiency was placed in front of the tape, where the activity was implanted. We chose a segmented 2×2 Multianode Hamamatsu PMT R7600U-M4 for the plastic detector. By requiring coincidences between the segments we could reduce the noise level and set an energy threshold of ∼ 70 keV.

The setup was completed with a HPGe detector placed behind the β plastic detector. It was used to identify possible contamination coming from the activity of the decay chain.

3. Detector performance

In order to determine a β-intensity distribution from the measured spectrum, a de-convolution has to be done with the spectrometer response to the decay [13]. For this purpose we have to solve the inverse problem represented by:

\[ d_i = \sum_j R_{ij} f_j \]  \hspace{1cm} (2)

where \( d_i \) is the number of counts in channel \( i \), \( f_j \) is the number of events that fed level \( j \) in the daughter and \( R_{ij} \) response function of the detector that represents the probability that feeding to the level \( j \) gives a count in channel \( i \) of the spectrum.

A method to de-convolute the feeding distribution has been developed [14] and successfully applied to previous measurements [1][2][3][15]. Since the response function is unique to each detector and each decay scheme, it has to be calculated via MC codes, with the geometry and the physics involved in the detection process. Hence, the key step in the characterization consists of simulating calibration sources to obtain the best match with the corresponding experimental measurements. For this purpose the package Geant4 [16] has been used and the detailed geometry of the DTAS, the ancillary detectors and the beam pipe has been included. In order to compare the experimental measurements and the simulations, any source of contamination has to be subtracted. In the case of the calibration sources apart from subtracting the environmental background, we have calculated the effect of random summing of signals from different detector modules and of pileup in a single detector module [17]. A Monte Carlo procedure to calculate both contributions based on the random superposition of two stored events within the ADC gate length was developed for previous works [10] and has been successfully applied here. As can be observed in Figure 3 we obtain an excellent reproduction of the measured spectrum with MC simulations.

![Figure 3: 24Na source produced at IGISOL. The background subtracted experimental spectrum (black) is compared with the MC (red) after adding the summing-pileup (blue).](image-url)

4. Selected case: 137I

As an example, we present here a preliminary analysis of the decay of 137I, an important β-delayed neutron emitter with \( P_n = 7.14\%\).
and \( T_{1/2}=24.5 \text{ s.} \) In this case \( Q_\beta=6.027 \text{ MeV} \) and \( S_n=4.025 \text{ MeV}, \) and it is known from high-resolution experiments \([18, 19]\) that \( \gamma \) emission competes with neutron emission above \( S_n. \) The rate was 350 nuclei/s and the decay of the daughter, \( ^{137}\text{Xe}, \) with \( T_{1/2}=3.83 \text{ min,} \) was also measured in order that it can be subtracted as a contaminant. Apart from the summing-pileup, an important source of contamination in this case are the neutrons released in the decay process that interact with DTAS. This contribution has been evaluated with Geant4 in the line of previous works \([5, 10, 20]\), using the ENDF-VII0 library and a modified neutron capture cascade generator. In particular, we observe in Figure 4 a peak at 6.83 MeV which comes from neutron capture in \( ^{127}\text{I}, \) while below 2 MeV inelastic interactions dominate.

The detector response to the decay was calculated using the known decay scheme at low excitation energies and the nuclear statistical model at high excitation energies. Figure 4 shows the quality of the reproduction of the measured spectrum with this response. From this preliminary analysis we obtain 8.7(10)% \( \beta \) intensity followed by \( \gamma \) emission above \( S_n, \) in contrast with the 2.75% reported in the ENSDF database \([21]\). The situation is similar to that found in the decay of \( ^{87}\text{Br} \) \([10]\).

The allowed decay of \( ^{137}\text{I} \) populates positive parity states with \( J=5/2, 7/2, 9/2 \) and the decay of such states to the 0\(^+\) g.s. of \( ^{136}\text{Xe} \) requires the emission of neutrons with large orbital angular momentum and is, therefore, hindered. In addition, a sizeable Pandemonium effect in the average \( \gamma \) and \( \beta \) decay energies is also found, as reported in Table 1.

5. Conclusions

The DTAS detector designed for DESPEC (FAIR) has been commissioned in the eighteen-module assembly with low energy radioactive beams at IGISOL. These measurements allowed us to perform a careful characterization of the DTAS detector response, as well as of the \( \beta \) plastic detector. A good agreement between calibration sources and MC simulations has been achieved, so that we are able to calculate the response function of the decays of interest, and carry out the analysis of the measured fission products. The overall good performance of the detector and the gain stabilization system have been demonstrated, and we have achieved a good understanding of the detector response. This is an important step towards the application of DTAS at FAIR with high energy beams.
