(Received 20 May 2016; revised manuscript received 30 June 2016; published 26 September 2016)

A powerful technique is introduced for simulating mechanical and electromechanical properties of one-dimensional nanostructures under arbitrary combinations of bending, twisting, and stretching. The technique is based on an unconventional control of periodic symmetry which eliminates artifacts due to deformation constraints and quantum finite-size effects and allows transparent electronic-structure analysis. Via density-functional tight-binding implementation, the technique demonstrates its utility by predicting nonlinear electromechanical properties in carbon nanotubes and abrupt behavior in the structural yielding of $\text{Au}_7$ and $\text{Mo}_6\text{S}_6$ nanowires. The technique drives simulations markedly closer to the realistic modeling of these slender nanostructures under experimental conditions.

DOI: 10.1103/PhysRevApplied.6.034014

I. INTRODUCTION

A significant part of contemporary nanomaterial research investigates one-dimensional (1D) nanostructures. Research motivations originate from a plethora of applications among medicine [1], nanoelectronics [2–5], nanomechanics [6–8], filters [9], sensors [10,11], material reinforcement [12], and the tailoring of material properties [13,14]. Some 1D nanostructures are best treated by periodic boundary conditions; extreme slenderness. Because of large aspect ratios, they are prone to bending, twisting, and stretching, along with their arbitrary combinations. Such deformations are ubiquitous in practice, as proven by numerous experiments [23–27].

However, just as eliminating deformations in experiments is hard, incorporating them into theory is even harder. All deformations are possible in finite structures, but related simulations are plagued by problems. First, most nanostructures have so many atoms that their straightforward simulation is simply out of question. Second, quantum simulations of finite structures are often deteriorated by finite-size artifacts. Third, unless specifically designed to mimic experimental settings, mechanical deformation constraints can sabotage the very phenomena under study. Fourth, electronic-structure analysis of finite constrained structures is often cumbersome. Therefore, 1D nanostructures are best treated by periodic boundary conditions, effectively modeling infinite extensions. Various loading conditions were investigated previously, but arbitrary deformations have always been simulated using finite structures [28,29]. Also, although recent methodological advances have enabled simulating periodic structures under pure twisting and pure bending [30–33], experimental deformations are rarely pure [34]. Electronic-structure simulations of 1D nanostructures with realistic, arbitrary deformations have remained elusive.

In this article, therefore, I introduce a technique to model 1D nanostructures with arbitrary deformations. Based on revised periodic boundary conditions, the technique eliminates artifacts related to quantum finite-size effects and mechanical deformation constraints. It also allows easy electronic-structure analysis in studies on electromechanics. I demonstrate the utility of the technique by revealing surprises in the electromechanical properties of carbon nanotubes and by predicting unconventional structural yielding behavior in $\text{Au}_7$ and $\text{Mo}_6\text{S}_6$ nanowires.

II. THE TECHNIQUE

A. 1D periodicity with customized symmetry

To first introduce notations, consider electrons in a potential $V(r)$ invariant under an isometric symmetry operation $\hat{D}(S)V(r) = V(S^{-1}r) = V(r)$, where $r' = Sr$. Since the Hamiltonian operator $\hat{H} = -\hbar^2/(2m_e)\nabla^2 + V(r)$ commutes with the operator $\hat{D}(S)$, the two operators share the same eigenstates. If we further assume a periodic boundary condition after $N$ successive operations of $\hat{D}(S)$—that is, $\hat{D}(S^N) \equiv \hat{I}$—the eigenstates acquire the property $\hat{D}(S^n)\psi_{\alpha\kappa}(r) = \exp(ikn)\psi_{\alpha\kappa}(r)$, where $n$ is the number of symmetry operations and $\kappa \in [-\pi,\pi]$ is a good quantum number used to index the eigenstates. Consequently, the wave function $\psi_{\alpha\kappa}(r)$ within a minimal unit cell determines the wave function in the entire extended structure. If the symmetry operation $S$ is the translation $T$, the above is obviously nothing but Bloch’s theorem in one dimension [35]. The theorem, however, applies also for symmetries beyond translation, although, as yet, few implementations exploit this feature [30,36].

The formalism of using symmetry and periodicity in this
generalized fashion is referred to as revised periodic boundary conditions (RPBCs) [32,33].

Consider, then, a one-dimensional nanostructure and the symmetry operation

$$r' = S_r r = R[\xi(\varphi_s)](R + R[\theta(\varphi_s)](r - R)), \quad (1)$$

where $R[\xi(\varphi)](v)$ represents the rotation of a vector $v$ an angle $\theta$ with respect to the axis $\hat{u}$, where the angles $\varphi_s$ and $\phi_s$ are small (Fig. 1). The successive operation of $S_r$ thus stands for a bending operation around the $z$ axis combined to a screw operation around a gradually reorienting chiral axis with a radius of curvature $R = |R|$. Compared to previous usages of symmetry, the operation (1) conceals one fundamentally unconventional feature: position dependence of the operation itself. This dependence makes the operation, in principle, nonisometric. It turns out, however, that if $\varphi_s$ or $\phi_s$ or both are small, and if atom positions $r_i$ in the nanostructure have the symmetry $r'_i = S_r r_i$, the property of isometry, the symmetry of the potential $V(S_r r) \approx V(r)$, and the commutation of operators $[\hat{D}(S_r r), \hat{H}] = 0$ become valid approximations. Because of the commutation of operators, in the spirit of revised periodic boundary conditions, $\psi_{\mu\kappa}(r)$ within a unit cell then suffices to describe the entire extended nanostructure (Fig. 1) [32,33]. Although physically sensible structures require that $\varphi_s$ and $\phi_s$ be integer fractions of $2\pi$, in practice their smallness renders such requirements irrelevant. That is, by requiring an interaction range to be small compared to $R$, bending, twisting, and stretching can be regarded as local deformations, as established previously [37--39].

Consequently, Eq. (1) becomes the foundation that enables effective modeling of 1D nanostructures with arbitrary deformations. Deformations are controlled via the parameters $R$, $\varphi_s$, and $\phi_s$ as follows. First, by considering a structure with diameter $D$, bending can be quantified by the strain $\Theta = D/(2R)$. In the absence of axial strain, the bending angle is $\varphi_s = \Theta D/R$, where $L_0$ is the cell length of the undeformed structure, and $\Theta$ equals the maximal tensile and compressive strains along the tangential direction. Second, chiral twisting can be quantified by the sidewall shear $\gamma = (D/2)\phi_s/L_0$. Third, axial strain can be quantified simply by $e = (L - L_0)/L_0$, where $L = R\varphi_s$ is the strained axial length. Thus, the three strains $(\Theta, \gamma, e)$ fully quantify arbitrary local deformations in 1D nanostructures. Note that deformations are created not by external constraints but by underlying symmetries; all atoms remain fully unconstrained.

**B. Density-functional tight-binding implementation**

I implemented the technique using the density-functional tight-binding (DFTB) method and the HOTBIT code [40,41]. Any classical force field or electronic-structure method would be equally suitable, but the DFTB formalism allows straightforward implementation and describes the energetics and electronic structures of covalent—and even metallic—systems with reasonable accuracy [40,42,43]. The pertinent parametrizations are adopted from Refs. [40,42,43].

According to the RPBC formalism [32,33], the DFTB electron wave functions under the symmetry (1) are described by the revised Bloch basis functions,

$$|\kappa, \mu \rangle = \varphi_{\mu}(\kappa, r) = \frac{1}{\sqrt{N}} \sum_n \exp(-i\kappa n) \hat{D}(S_r^n) \varphi_{\mu}(r), \quad (2)$$

where $\varphi_{\mu}(r)$ represents a minimal set of local orbitals and $\sum_n 1 = N$ is the number of unit cells. On this basis, the Hamiltonian is diagonal in $\kappa$,

$$\langle \kappa, \mu | \hat{H} | \kappa', \nu \rangle = \delta(\kappa - \kappa') \sum_n \exp(-i\kappa n) H_{\mu\nu}(n), \quad (3)$$

where the Hamiltonian matrix elements are

$$H_{\mu\nu}(n) = \int \varphi_{\mu}^*(r) \hat{H}(S_r^n) \varphi_{\nu}(r) d^3 r. \quad (4)$$

Together with analogous equations for overlap matrix elements, the DFTB total-energy expression is as usual [40,41], forces are calculated as parametric derivatives of the total energy, and structural relaxation and molecular dynamics are performed in the usual fashion [41]. The positions of atoms’ periodic images are mapped exactly via Eq. (1), but, for simplicity, the orbital rotations $\hat{D}(S_r^n) \varphi_{\mu}(r)$

FIG. 1. Deformed 1D nanostructure. Atoms obey the symmetry operation $r' = S_r r$ [Eq. (1)]. Arbitrary deformations can be created by simultaneous adjustments of bending (via $\varphi_s$ and $R = |R|$), twisting (via $\phi_s$), and stretching (via $R$ and $\varphi_s$). The chiral-symmetry axis (the dashed curve) lies in the $x$-$y$ plane. The red shaded area sketches the simulation cell.

![Image](https://example.com/image.png)
in Eq. (4) are done using the averaged tangential vector of \( \mathbf{t} = -\sin(\varphi_s/2)\hat{x} + \cos(\varphi_s/2)\hat{y} \).

Finally, although the concept of a unit cell is familiar, conceptually intuitive, and visually helpful, here such a concept is, in principle, unnecessary. Unit cell is even sketched in Fig. 1, but in practical implementation it is nowhere to be found, because DFTB only requires atoms’ relative positions, which are fully determined by Eq. (1). Atoms do not need to remain inside a certain spatial region.

### C. Deformation simulations

Deformation simulations began with initial guesses for the positions of each atom \( I \) that are determined from

\[
r_I = \mathcal{R}[\hat{z}(\varphi_s)] \{ [\mathbf{R}\hat{x} + \mathcal{R}[\hat{y}(\varphi_s)](\bar{x}_I\hat{x} + \bar{z}_I\hat{k})] \},
\]

where \( \mathbf{r} = \bar{x}_I\hat{x} + \bar{y}_I\hat{y} + \bar{z}_I\hat{k} \) represents atom positions in an undeformed 1D nanostructure centered around the \( y \) axis. The length of the structure is \( L \), which means that the variable \( \chi = \bar{y}_I/L \) ranges from \( \chi = 0 \) to \( \chi = 1 \). Simulations then continue either by structural relaxation, using the fast inertial relaxation engine optimizer [44], or by molecular dynamics simulations using a Langevin thermostat with a 10-K temperature and a 0.5-ps damping time.

Two notes are worth mentioning here. First, if \( \varphi_s = 0 \), then the symmetry operation becomes

\[
r’ = \mathcal{S}_r \mathbf{r} = \mathcal{R}[\hat{z}(\varphi_s)](\mathbf{r}),
\]

which makes \( \mathcal{S}_r \) independent of \( \mathcal{R} \). Therefore, in the general case, the radius of curvature for an untwisted, relaxed structure could not be controlled by \( \mathcal{S}_r \); for a structure with the symmetry \( C_m \), control can be regained by setting \( \varphi_s = 2\pi/n \), thus mimicking the untwisted structure of a chiral-symmetry operation. Second, the eigenproblem faces occasional technical difficulties when the simulation cell is small and orbitals interact with their own periodic images; longer simulation cells eliminate these difficulties.

### III. DEFORMED CARBON NANOTUBES

#### A. Validation of the technique

To validate the technique, I begin by investigating single-walled carbon nanotubes (CNTs). They provide a good benchmark for testing because their mechanical properties were investigated thoroughly in the past [45–50]. For example, it was shown that the energetics of carbon nanotubes with a sufficiently large diameter follow closely the classical thin-sheet elasticity theory with elastic parameters adopted directly from graphene [45,51].

For completeness and for later reference, before proceeding with arbitrary deformations, I verify the thin-sheet model with pure bending, pure stretching, and pure twisting of CNTs. The deformation energies under pure deformations agree very well with pertinent analytical estimates, where the related elastic parameters, the Young’s modulus \( Y = 25.5 \text{ eV/Å} \) and the Poisson ratio \( \sigma = 0.285 \), are calculated for graphene by DFTB (Fig. 2). In addition to linear elasticity, nonlinear (bond anharmonicity) effects cause CNT stretching upon bending, because bonds at inner edge compress less than bonds at outer edge elongate [52]. Assuming a strain-dependent Young’s modulus of the form \( Y = (1 - \beta \varepsilon)Y_0 \), with the anharmonicity parameter \( \beta = 1.7 \) [52], the analytically calculated axial strain upon bending becomes \( \varepsilon_\theta = \frac{1}{2} \beta \Theta^2 \), as confirmed by simulations [Fig. 2(b)].

To create arbitrary deformations, I use a four-stage deformation path,

\[
(\Theta, \gamma, \varepsilon)(s) = \begin{cases} (\varepsilon_0, 0, 0) & \text{for } s \in [0, 1], \\
(e_0, e_0(s-1), 0) & \text{for } s \in [1, 2], \\
(e_0, e_0, 0(s-2)) & \text{for } s \in [2, 3], \\
(e_0, e_0, e_0)(4-s) & \text{for } s \in [3, 4], \end{cases}
\]

where \( \varepsilon_0 \) is a maximum strain and \( s \in [0, 4] \) is a deformation coordinate. That is, deforming begins with pure bending, proceeds with additional twisting and then by stretching, and terminates with the synchronous reversal of bending, twisting, and stretching (Video 1). The energy per unit length in a CNT under the deformation \( (\Theta, \gamma, \varepsilon) \) is

\[
E(\Theta, \gamma, \varepsilon)/L_0 = \frac{\pi DY}{4} \left( \Theta^2 + \frac{1}{1+\sigma} \gamma^2 + 2\varepsilon^2 \right),
\]

where the set of selected tubes is listed in Fig. 5.) (a) Energy per sidewall area for CNTs under pure bending. The dashed line is the curve \( E/A = \frac{1}{2} Y\Theta^2 \). (b) Axial stretching induced by pure bending. The dashed line is the curve \( e_\theta = \frac{1}{2} \beta \Theta^2 \). (c) Energy per sidewall area for CNTs under pure stretching. Dashed line is the curve \( E/A = \frac{1}{2} G\gamma^2 \), where \( G = Y/(1 + \sigma) \) is graphene’s shear constant.
which is a superposition of energies under separate pure deformations (Fig. 2). Now, as demonstrated for an (11, 0) CNT, energy from the periodic technique agrees with Eq. (8) to high accuracy [Fig. 3(a)]. That is, deforming a CNT merely by adjusting the symmetry operation $S_\gamma$ gives accurate deformation energies. I emphasize that this agreement is not trivial, because in periodic quantum simulations the elastic properties are a priori indeterminate; they emanate automatically from the electronic structure, from wave functions, and from wave-function symmetries. The agreement can therefore be considered as a direct validation for the technique and a verification of the underlying approximations.

**C. Electromechanics under arbitrary deformations**

The DOS for the (11, 0) CNT [Fig. 3(b)] is also recorded for the entire deformation path. Upon deforming the van Hove singularities remain prominent, but they shift to higher and lower energies [Fig. 4(a)]. These shifts are reflected by changes of the fundamental energy gap, as reported earlier for pure deformations [52,54–57]. Regarding arbitrary deformations, it turns out that the gap is well described by

$$\mathcal{E}(\Theta, \gamma, \epsilon) = \mathcal{E}(0, 0, 0) + \Delta \mathcal{E}_{||}(\epsilon_0 + \epsilon) + \Delta \mathcal{E}_\perp(\gamma),$$  

(9)

where $\Delta \mathcal{E}_{||}(\epsilon) = \mathcal{E}_{||}(\epsilon) - \mathcal{E}_{||}(0)$ is the gap change under pure axial strain and $\Delta \mathcal{E}_\perp(\gamma)$ the corresponding gap change under pure twist [Fig. 4(b)]. Equation (9) also includes contribution from axial strain due to bond anharmonicity, as discussed above [52,57]. This effect is visible at $s < 1$, where $\gamma = \epsilon = 0$ but $\epsilon_0 \neq 0$ [Fig. 4(b)]. Thus, gap changes under arbitrary deformations are given by linear superposition of gap changes in separate pure deformations. Because the superposition is valid for all van Hove singularities, Eq. (9) is expected to pertain to optical transitions as well [56]. The validity of linear superposition could be anticipated, but it has never been demonstrated directly.
The news is, however, that sometimes the superposition principle goes awry without warning. When considering an (8, 4) CNT under the path with \( \epsilon_0 = 5\% \), after \( s \gtrsim 2 \), the gap starts to behave in a manner opposite to that displayed in Eq. 9 [Fig. 2(c)]. In an (8, 4) CNT, pure stretching increases the gap [see the inset of Fig. 2(c)], but the stretching of the already-bent-and-twisted tube decreases the gap. The combination of deformations creates a synergy that causes a nonlinear response in the electronic structure and invalidates linear superposition. For an (8, 4) CNT, the validity of Eq. 9 is regained by decreasing \( \epsilon_0 \) down to 2\% (not shown), but the limits of validity cannot be anticipated from CNT electromechanics under separate pure deformations; confirmation of possible validity requires explicit simulations with arbitrary deformations.

I repeat the above analysis with \( \epsilon_0 = 5\% \) for a set of different chiral and nonchiral CNTs. It turns out that the superposition equation 9 is most accurate for zigzag and armchair tubes and slightly less accurate for chiral tubes (Fig. 5). The origin for this behavior is unknown and requires further investigation.

D. Poynting effect

To return to the mechanical properties of CNTs, previous simulations have already shown that chiral tubes display the Poynting effect, which means that stretching and twisting are coupled (twisting induces stretching, or the other way around) [48]. While predictions have been made using purely classical models, the predictions here are confirmed by a quantum-mechanical method (Fig. 6).

Given the Poynting effect, the bending-induced axial stretching [Fig. 2(b)], and the technique for simulating arbitrary deformations, it is pertinent to investigate whether bending could also induce twisting in CNTs. The twisting angle attributable to bending can be roughly estimated as

![](FIG. 4. CNT electromechanics under arbitrary deformations. (a) Contour plot for the density of states (DOS) of (11, 0) CNT under the deformation path of Eq. (7) with \( \epsilon_0 = 5\% \). (b) Energy gap of (11,0) CNT derived from (a) (the circles) and from the estimate of Eq. (9) (the solid line). (Inset) Energy gap of (11, 0) CNT as a function of pure stretching (\( E_\parallel \)) and pure twisting (\( E_\angle \)). (c) The same as (b) for an (8, 4) CNT.

![](FIG. 5. Electromechanics of various CNTs under arbitrary deformations. (a) Energy gap under pure shear (the red lines) and pure stretch (the blue lines), defining the functions \( E_\parallel (\epsilon) \) and \( E_\angle (\gamma) \). (b) Energy gaps under the deformation path of Eq. (7). The solid lines are estimates from Eq. (9), using the data from (a). (c) Contour plot for the density of states under the deformation path of Eq. (9). The color scale is the same as in Fig. 4(a). The parameter \( \epsilon_0 = 5\% \) is used in (b) and (c).
\[ \Delta \gamma = \frac{\partial \gamma}{\partial \varepsilon} \times \frac{3}{2} \beta \Theta^2, \]

where \( \frac{\partial \gamma}{\partial \varepsilon} \) measures the magnitude of the Poynting effect. At its maximum, the magnitude is \( \frac{\partial \gamma}{\partial \varepsilon} \mid_{\text{max}} \approx 0.1 \) (Fig. 6), so the largest amount of bending-induced twisting becomes \( \Delta \gamma \approx 0.13 \times \Theta^2 \), which turns out to be only \( \Delta \gamma \approx 0.1\% \), even with bending as large as \( \Theta \approx 10\% \). A CNT with \( D = 1 \) nm bent to \( \Theta = 1\% \) would then need to be at least a quarter of a millimeter long to twist a full turn. Being this tiny in magnitude, bending-induced twisting could not be resolved in periodic simulations. Zhao and Luo [50] reported twisting-induced bending, but it was due to the Poynting effect combined to a constrained length for a finite tube; intrinsic bending-induced stretching in CNTs seems to be too minor to be of practical significance.

IV. DEFORMED MoS AND Au NANOWIRES

A. Electromechanics of MoS\(_2\) nanowire

Let us next leave CNTs aside and move on to study MoS\(_2\) monolayer-derived Mo\(_6\)S\(_6\) nanowires [42,58–60]. These wires are a timely example of deformed 1D nanostructures, as demonstrated by aberration-corrected transmission electron micrographs [60]. For example, the work of Lin et al. shows highly resilient Mo\(_6\)S\(_6\) nanowires bent up to \( \Theta \approx 6\%–10\% \) [61]. Undeformed Mo\(_6\)S\(_6\) wires are metallic, but the twist of magnitude \( \gamma = 2.7\% \) (assuming the wire diameter \( D = 0.3 \) nm) is predicted to open a gap, which is also confirmed here [Fig. 7(a)] [4]. As suggested before, these properties can be exploited in an electromechanical switch that allows current propagation in a straight wire but not in a twisted one [4]. Here, simulations agree with the previous results under pure bending and pure twisting, but the analysis is more transparent, as the band structure can always be plotted for the same minimal cell. Analysis reveals that pure bending creates small energy splittings due to weak wave-function localization at inner and outer sides of the wire [Fig. 7(b)]. Analogous localization has also been reported in the vibrational modes of bent CNTs [37]. Pure bending affects band structure weakly, but a preexisting twist enhances the effect of bending notably [juxtapose the changes in Fig. 7(b) from upper left to upper right with the changes from lower left to lower right]. However, although the twisting-induced metallic-to-semiconducting transition is seen here also under bending, a robust electromechanical switching operation should also require structural robustness; we discuss this matter next.

B. Mechanical stability of Mo\(_6\)S\(_6\) nanowire

The reliability of a structural-stability analysis calls for larger simulation cells than the minimal ones. With the minimal 12-atom cell, Mo\(_6\)S\(_6\) is stable at least beyond \( \Theta = \gamma > 4\% \), as shown above [the lower-right panel in Fig. 7(b)]. When the simulation cell length is extended to 2.6 nm, however, the atomic structure reveals its sensitivity to combined deformations. When twisted, the elastic energy first depends quadratically on \( \gamma \), with the torsion constant 150 eV Å, in fair agreement with the literature [59]. Upon further twisting, the energy starts to deflect from this quadratic trend and the wire begins to yield [inset of Fig. 8(a)].
C. Mechanical stability of Au\textsubscript{7} nanowire

I perform a similar stability analysis for a 0.6-nm-diameter Au\textsubscript{7} nanowire with 1.7-nm-long cells [43]. This nanowire shows yield limits qualitatively similar to those of Mo\textsubscript{6}S\textsubscript{6} [Fig. 8(b)]. Atom trajectories reveal that yielding occurs for the entire wire cross section at once, collectively, which helps us to appreciate the qualitatively different behavior compared to macroscopic rods and wires. Earlier studies of Mo\textsubscript{6}S\textsubscript{6} and Au wires revealed several dislocations, which could be indirect indications of the low yield limits under combined deformations [19,59,63]. Yet, this yielding behavior remains a puzzle that deserves further investigation.

As a final observation, bending and twisting in Au\textsubscript{7} turn out to be coupled [see the inset of Fig. 8(b)]. At a given $\Theta$, the energy is minimized at the varying twist $\gamma_0$, following $\gamma_0(\Theta) \approx 0.02 + 0.28 \times \Theta$. That is, unlike in CNTs, in Au\textsubscript{7}, bending induces twisting and twisting induces bending, as is familiar from mechanical springs [64].

V. CONCLUSIONS

To conclude, I hope to have demonstrated that for a faithful modeling of the mechanical and electromechanical properties of 1D nanostructures, simple modeling with separate pure deformations is insufficient—explicit simulations of combined deformations are mandatory. Demand for such simulations grows as the control over 1D nanostructures improves. Perspective for this demand can be obtained by considering the list of related nanostructure examples, which includes metal, semiconductor and molecular nanowires, DNA, polymers, single- and multi-walled CNTs, CNT ropes and bundles, and nanoribbons of graphene and other 2D materials, among many others. Particularly relevant are their surface functionalizations, which are bound to cause complex deformations.

ACKNOWLEDGMENTS

I thank Jyri Lahtinen for his contributions during the early stages of the project, Petri Luosma for his comments, the Academy of Finland for the funding (Projects No. 283103 and No. 251216), and the CSC—IT Center for Science in Finland for the computer resources.
