Abstract

In this study, the potential of organic acids (formic acid, acetic acid) in a catalytical and mechanocatalytic conversion of lignocellulosic barley straw to valuable sugars is explored using sulfuric acid as a reference. Acid-catalyzed hydrolysis has been carried out with acid-impregnated samples as well as unmodified barley straw. In the mechanocatalytical approach, pretreatment consists of impregnation with the acid catalyst and mechanical treatment by ball milling following chemical hydrolysis. Straw samples and residues were analyzed by Fourier transform infrared spectrometry (FT-IR) whereas hydrolysate analysis was based on total reducing sugar (TRS) determination following the DNS method and capillary electrophoresis (CE) analysis. The results indicated that acetic acid and formic acid are rather mild acids yielding low TRS levels compared to the reference acid. Mechanocatalytical pretreatment slightly increased TRS yields, but not significantly. Strikingly, sulfuric acid showed an efficient conversion efficiency yielding almost 45% of TRS. Furthermore, this study provided evidence for the acetylation of straw components when acetic acid was used as catalyst. Alkali hydrolysis induced the de-esterification, but revealed no significant increase of TRS yields.

Keywords: Barley straw, Lignocellulose, Formic acid, Acetic acid, Mechanocatalytical conversion

1. Introduction

Strengthening the commitment of renewable energy sources is one of the major bioeconomy challenges in order to safeguard a sufficient supply of energy and to reduce greenhouse gas emissions. The European Commission states the binding target in the EU’s Renewable Energy Directive (2009/28/EC) that 20% of final energy consumption should be derived from renewable sources as well as a minimum of 10% of transportation fuels, both by 2020 [1]. Moreover the targets for 2030 include at least a 27% share of renewable energy consumption, a 30% improvement in energy efficiency as well as a 40% cut in greenhouse gas emissions compared to the levels in 1990 [2]. Biomass is a strong growing stock of natural raw material source which has high potential for contribution in the sustainable production of energy, biofuels and biochemicals. Generation of
bioenergy from renewable resources lowers CO₂ emissions and decreases the dependence on energy imports and fossil materials whose reservoirs are about to run out. Biomass can be efficiently recycled by catalytic conversion to carbohydrates which can in turn be converted to biofuels such as ethanol and butanol, e.g. by gasification (Fischer-Tropsch process) or fermentation [3]. These days, bioethanol production derives predominantly from the turnover of food supply chain products such as corn, beet and cane sugar. This is clearly not sustainable and conflicts with food and feed production security. Biomass does not interfere with food production. In this study, barley straw is explored for its potential as a raw material for catalytic and mechanocatalytic conversion to valuable sugars. Barley straw, as a second generation biomass, belongs to the lignocellulosic resources group whereas starch and sugar-based raw materials represent first generation biomass.

Currently, less commercial technological applications for biofuel production exist which requires the establishment of innovative techniques. The present research aims at the determination of the efficiency of acetic acid and formic acid as a catalyst in catalytic and mechanocatalytic fractionation of lignocellulosic barley straw to valuable carbohydrates. The mechanocatalytic approach, schematically illustrated in Figure 1, is carried out under solvent-free conditions by the combination of chemical catalysis and mechanical assisted processing. The conversion of lignocellulosic barley straw into sugars is a two-step process which includes the impregnation of the material with an acid catalyst in the first step and mechanical treatment driven by milling in the second leading to the disruption of the lignocellulosic matrix [4]. Resulting oligosaccharides from the conversion reaction are hydrolyzed yielding monosaccharides [3]. These mechanocatalytically obtained sugars constitute the basic product for the formation of biofuels with high conversion efficiency.

2. Results and Discussion

2.1. Elemental and structural analysis of barley straw

Elemental analysis revealed a total carbon content of 45.4 wt.%, nitrogen content of 2.5 wt.% and hydrogen content of 5.7 wt.% calculated from dry material which is comparable to literature [5, 6]. Nitrogen content appeared to be increased by about a factor of 4 which might indicate an increased protein level. However, the protein content is of minor interest in this study and was not separately determined.

Structural analysis of barley straw was carried out by Fourier transform infrared spectrometry (FT-IR) which provides detailed information on the chemical bonds in the molecules. The recorded spectrum is illustrated with a reference spectrum of alpha-cellulose in Figure 2. The absorption band at 3333 cm\(^{-1}\) shows a broad peak for intra and intermolecular hydrogen bonded OH-groups in C2, C3 and C6 position of the glucose units of cellulose. The two bands at 2918 cm\(^{-1}\) and 2851 cm\(^{-1}\) represent C-H stretching for aliphatic saturated compounds which is attributed to the CH\(_2\) stretch vibration from the CH\(_2\)OH group of C6 in cellulose. Characteristic in the fingerprint region is the sharp and strong band at 1026 cm\(^{-1}\) which also occurs in the alpha-cellulose FT-IR spectrum. It represents the C-O-C ether vibration in cellulose and hemicellulose and the C-O stretching in cellulose, hemicellulose and lignin [7]. The band of the barley straw spectrum is more distinct and intense due to its complex matrix including hemicellulose [8].

Figure 2. FT-IR spectrum of barley straw (red) (particle size: 0.5 mm) and alpha-cellulose (black).
2.2. Effect of different acid catalysts on the total reducing sugar (TRS) yield of barley straw hydrolysates

Prior to the mechanocatalytic treatment with the ball mill, solely acid-catalyzed hydrolysis of impregnated as well as non-impregnated barley straw samples was performed. The results are shown in Figure 3. It can be clearly seen that total reducing sugar (TRS) analysis of non-impregnated straw revealed significant high yield for barley straw when it is hydrolyzed with 2 mmol of sulfuric acid per gram straw sample at 100°C. TRS release decreased 5 to 9 times when the same concentration of formic acid and acetic acid was applied. Similar results could also be observed for acid-impregnated straw samples which have been in contact with the respective acid for 30 min prior to hydrolysis.

To find out whether a higher concentration of organic acid results in higher TRS yields, barley straw was impregnated with a 3 times higher formic acid concentration (6 mmol/g). However, similar TRS yields were achieved. In general, hydrolysis at room temperature yielded lower TRS release compared to hydrolysis at 100°C. Exclusively acetic acid yielded a higher TRS result at room temperature than at 100°C which might be associated with its boiling point at 118°C. However, straw hydrolysis with acetic acid performed at a lower temperature (80°C) revealed only a slight increase in TRS yields. Surprisingly, hydrolysis merely with distilled water at 100°C without the addition of an acid catalyst yielded higher TRS levels than organic acid hydrolysis.

Figure 3. TRS yield of hydrolysates from impregnated and non-impregnated barley straw with different acid catalysts at room temperature (RT) and 100°C.
Since TRS yields from straw hydrolysates catalyzed with organic acids were relatively low compared to hydrolysis with the mineral acid, it raised the question whether barley straw was sufficiently loaded with the respective organic acids. Figure 4 shows the FT-IR spectrum of unmodified barley straw and acetic acid-impregnated barley straw. Major differences between the two spectra occurred in the band at 1731 cm\(^{-1}\) which was only present in the impregnate. The band represents the acetyl C=O stretching band from acetic acid which confirmed the successful loading of the straw sample. However, the band is not as strong as expected. Hence, the amount of loaded acid was identified by titration with a sodium hydroxide solution. Strikingly, impregnated straw samples revealed an acid loading of 14.8 % acetic acid, 30.9 % formic acid and 70.8 % sulfuric acid. These results clearly indicated that the impregnation of barley straw with the tested organic acids is somehow hampered whereas sulfuric acid could be loaded relatively efficiently. However, the acid loading appears to not have a significant effect on TRS yields. It has been shown above that TRS yields of hydrolyzed impregnated straw samples were similar to the TRS releases of non-impregnated hydrolysates in which the acid catalyst was added shortly before the hydrolysis process in the same concentration. Another possible explanation for the low TRS yields could be the inhibition of sugar generation due to the formation of by-products. It has been reported that the hydrolysis of lignocellulosic biomass
leads to the formation of furfural, hydroxymethyl furfural, complex esters, humins and tars. Depending on the hydrolysis process conditions, these by-products can reduce the TRS yields [9]. Furthermore, formic acid and acetic acid represent mild C1 and C2 organic acids with a pKa of 3.7 and 4.7, respectively. Sulfuric acid, in contrast, is a strong diprotic acid whose proton is more likely donated to the solvent. Formic acid and acetic acid stay as non-ionized acids following the equations with acidity constants (K\textsubscript{a}) below [10].

\begin{align*}
\text{H}_2\text{SO}_4 + \text{H}_2\text{O} & \rightleftharpoons \text{H}_3\text{O}^+ + \text{HSO}_4^- & K_a &= 1.0 \times 10^2 \\
\text{HSO}_4^- + \text{H}_2\text{O} & \rightleftharpoons \text{H}_3\text{O}^+ + \text{SO}_4^{2-} & K_a &= 1.2 \times 10^2 \\
\text{CH}_3\text{COOH} + \text{H}_2\text{O} & \rightleftharpoons \text{H}_3\text{O}^+ + \text{CH}_3\text{COO}^- & K_a &= 1.7 \times 10^{-5} \\
\text{HCOOH} + \text{H}_2\text{O} & \rightleftharpoons \text{H}_3\text{O}^+ + \text{COO}^- & K_a &= 1.8 \times 10^{-4}
\end{align*}

In addition, it has been pointed out that contacting lignocellulosic biomass with acetic acid may result in the acetylation of its compounds such as cellulose and hemicellulose [9]. Solely, hydrolysis of the impregnated sample without any additional catalyst may not break the acetylated cellulose and hemicellulose and moreover, affect their turnover to sugars. Deacetylation is achieved by chemical hydrolysis with an alkali compound. Hence, supplementation of a base catalyst was carried out in order to induce de-esterification which might result in increased TRS yields. The results will be discussed in the following section.

2.3. Effect of alkali hydrolysis on the TRS yield from barley straw impregnates

Chemical reaction between the barley straw components and acetic acid may occur in form of an acetylation [9]. Hemicellulose and cellulose hold reaction sites which enable an acetylation on an alcohol function as shown schematically in the following figure:

![Figure 5. Schematic reaction of the acetylation of cellulose during hydrolysis with acetic acid.](image-url)
De-esterification of the acetate groups is catalyzed by alkali hydrolysis. In the present study, the acylated compounds are broken by chemical hydrolysis using sodium hydroxide and ammonium hydroxide as the catalyst. Straw was impregnated with acetic acid assuming that hemicellulose and cellulose undergo acetylation. The hydrolysis was subsequently carried out with an excess of catalyst attaining pH 14 and pH 10, respectively. During hydrolysis with NaOH, the formation of a swollen bulk could be observed which is associated with the mercerization process, a chemical treatment applied in the textile industry.

Strikingly, FT-IR analysis of the hydrolysis residue demonstrated that the acetyl groups were successfully removed. Figure 6 illustrates the spectra of barley straw impregnated with acetic acid, NaOH-hydrolyzed impregnate and NH₃-hydrolyzed impregnate. The spectra show that the ester bands of the impregnated straw disappear in the alkali hydrolyzed samples. The ester bands comprise the acetyl C=O stretching band of esters at 1731 cm⁻¹, the signal at 1369 cm⁻¹ attributed to the C-H in -O(C=O)-CH₃ and the C-O stretching of acetyl group at 1234 cm⁻¹ [7, 11]. Furthermore, alkali hydrolysates were free of esterified acetic acid which is demonstrated by the missing band at 1700 cm⁻¹ for a carboxylic group [9]. These results indicated that barley straw compounds were partly acetylated when contacted with acetic acid. In addition, hydrolysis of the impregnate with alkali compound succeeded in de-esterification of the acetylated straw constituents.

Figure 6. FT-IR spectrum of barley straw impregnated with acetic acid (blue), NaOH-hydrolyzed impregnate (black) and NH₃-hydrolyzed impregnate (red). Arrows indicate the three characteristic ester bands at 1731 cm⁻¹, 1369 cm⁻¹ and 1234 cm⁻¹.
The straw hydrolysates which were obtained by alkali hydrolysis either with sodium hydroxide or ammonium hydroxide, have been analyzed for their TRS yield. The results are depicted in Figure 7 which revealed that hydrolysis of the acetic acid-impregnated samples with ammonium hydroxide is more effective than hydrolysis with sodium hydroxide. Furthermore, an increase in TRS yield by a factor of 1.5 could be achieved by raising the hydrolysis temperature to 127°C. Alkali hydrolysis of unmodified barley straw which was not impregnated with acetic acid, was also analyzed. TRS results were similar or slightly higher compared to acid-impregnated straw samples hydrolyzed with the corresponding base catalysts.

Comparing the results of alkali hydrolysis with the earlier results obtained for hydrolysis of acetic acid-impregnated straw, it can be pointed out that TRS yields were higher when no base catalyst was supplemented for the hydrolysis reaction. The results indicated that sodium hydroxide and ammonium hydroxide were not efficient enough to convert straw compounds to valuable carbohydrates under the conditions applied in this study. Though an excess of base catalyst induced de-esterification, the efficiency for the conversion of lignocellulosic biomass was not sufficient.

### 2.4. Effect of mechanically solid state depolymerisation on the TRS yield of barley straw

Mechanical treatment by milling is a potential method for “cutting” the lignocellulosic biomass and increasing the availability of cellulose for catalytic conversion into sugars. Milling reduces the straw particle size and crystallinity and at the same time increases the specific surface area and supports the depolymerisation of the lignocellulosic material. The structural changes induced by the milling process imply an increase in TRS release.
In this section, the effect of ball milling prior to acid-catalyzed hydrolysis will be analyzed and discussed. According to the above mentioned results acetic acid and formic acid only released small amounts of total reducing sugar from the cellulosic material by hydrolysis. Sulfuric acid was emphasized as an effective acid catalyst for the conversion of lignocellulosic material from barley straw to valuable sugars. Figure 8 depicts the TRS yields of mechanocatalytically pretreated barley straw samples impregnated with sulfuric acid, formic acid and acetic acid. In principal, TRS release increased when milling was applied, except for impregnation with 2 mmol of formic acid per gram straw sample. Sulfuric acid-impregnated straw significantly produced the highest sugar amount. When hydrolysis was carried out with high temperatures, an 11 to 21 times increase in TRS compared to organic acid-impregnates was observed. Strikingly, 44.41 % fermentable sugars were obtained when sulfuric acid was used as a catalyst. Capillary electrophoresis (CE) measurement revealed a yield of 6.4 g glucose and 7.4 g xylose per 100 g of starting material at elevated temperature whereas 2.1 g glucose and 3.1 g xylose were formed at room temperature. Formic acid-based conversion generated little glucose (0.8 % at 100°C, 1.5 % at RT) and arabinose (0.32 % at 100°C, 0.8 % at RT). Xylose yields were under the limit of quantification. Surprisingly, acetic acid-catalyzed turnover showed a yield of 7.1 g glucose and only 0.8 g xylose per 100 g of barley straw when hydrolysis was carried out at room temperature which accounts for a total fermentable sugar release of 8.96 %. It can be pointed out that a higher glucose fraction in relation to total reducing sugar yield was released when formic acid was used as a catalyst. However, the total reducing sugar yield is five times less compared to sulfuric acid-based conversion. Xylose is additionally generated in adequate yields when sulfuric acid is used as catalyst. Furthermore, arabinose, galactose and sucrose could be determined, however in insignificant concentrations. The comparatively high TRS release of almost 45 % may be due to the presence of gluco- and xylo-oligosaccharides which have not been hydrolyzed completely [12].

The corresponding FT-IR spectra in Figure 9 show the changes in the cellulosic material by milling. The relative band height (distance from baseline to adjacent valley) at 1029 cm\(^{-1}\) which represents the C-O-C ether vibration in cellulose and hemicellulose, significantly decreased in the grinded straw sample, impregnated with sulfuric acid. These changes in cellulosic material arise from the decrease in the degree of crystallinity and polymerization which indicate the conversion of cellulose [8]. An increase in organic acid concentration repeatedly did not affect the TRS release. These results highlighted sulfuric acid as the most efficient conversion catalyst for barley straw among the tested acids. The enhancing effect of ball milling was substantially visible for sulfuric acid-impregnated straw samples which yielded almost 45 % TRS release. Absence of a mechanical treatment revealed a TRS yield of 17 % (see Figure 3) indicating that with the inclusion of mechanical treatment, TRS release almost triples under the milling conditions applied in this study.
Figure 8. TRS yield from mechanocatalytically pretreated barley straw with different acid catalysts (left) and illustration of the mechanical treated acid-impregnated straw as well as the hydrolysates (right).

Figure 9. FT-IR spectrum of ball milled barley straw samples impregnated with acetic acid (1), formic acid (2) and sulfuric acid (3) before hydrolysis revealing the changes in the cellulose backbone with the band at 1029 cm\(^{-1}\).
Remarkably, the color of the straw sample which was impregnated with sulfuric acid, turned dark greenish-brown after mechanical treatment (see Figure 8). Impregnation with organic acid did not drastically change the typical straw color. Each sample was treated the same and grinded for a total milling time of 1 h including breaks of 10 min after every 5 min grinding in order to avoid overheating and burning of the sample. The hydrolysate solutions of organic acid hydrolysis were pale yellow whereas the hydrolysate using sulfuric acid as a catalyst turned dark red-brownish. The reason for the color change is not yet known and should be subject to further analysis. It can be assumed that a colored substance was formed rather than the event of a carbonization process. The corrosive character of sulfuric acid combined with mechanical treatment which enhances the reaction contact sites between acid and organic material, may contribute to the appearance of the red-brownish color. Figure 10 depicts the barley straw sample at different stages of the mechanocatalytical process using formic acid and sulfuric acid as catalysts. Here, the color change is clearly visible when sulfuric acid was used as a catalyst. Already the unground, but impregnated sample was slightly darker in color compared to the pale yellow untreated barley straw. Interestingly, no residue was found after hydrolysis of the grinded sample which assumes that the straw compounds have been completely converted. Another possibility is the formation of a colloidal solution. Related to formic acid-impregnated samples, the color stayed pale yellow during the whole treatment process and resulted likewise in a pale yellow-colored hydrolysate as illustrated in Figure 8.

Figure 10. Barley straw processing chart for formic acid (up) and sulfuric acid (down) treated samples revealing the change in particle size and color.
3. Conclusions

Biomass is a significant resource for biofuel production which is not yet used to its full potential. New innovative scientific research concerning the construction of efficient technologies, methods and installations plays a key role in order to enhance the contribution of biomass as a renewable energy source for biofuel production. In this study, barley straw was investigated as a potential candidate for its fractionation into valuable carbohydrates using acetic acid, formic acid and sulfuric acid as a catalyst. It turned out that sulfuric acid significantly generated the highest yield of total reducing sugar in a mechanocatalytic approach, though a bioeconomic solution including formic acid and acetic acid was prioritized in this study. The catalytic conversion efficiency on hydrolysis of lignocellulosic straw material can be displayed as follows: Sulfuric acid >> formic acid > water > acetic acid. Sulfuric acid-catalyzed hydrolysis combined with mechanical treatment revealed a reasonable yield of 45 % fermentable sugars. The results verified barley straw as a feasible feedstock in sugar generation for the production of transportation biofuels and biochemicals yielding the replacement of conventional biofuels combined with greenhouse gas emission savings.

Continuing research will focus on the optimization of the mechanocatalytic fractionation of barley straw using sulfuric acid as a catalyst. The present study showed that mechanical treatment in combination with high temperature hydrolysis in an acidic environment were required for a sufficient conversion efficiency of cellulose and hemicellulose into carbohydrates.

4. Experimental Section

4.1. Raw materials

Barley straw examined in the present study was provided from a local Finnish farmer. The straw was dried and grinded to a particle size of 0.5 mm using a Retsch SM100 Comfort cutting mill. Other chemicals included: Formic acid (98-100 %, Merck), acetic acid (99-100 %, J.T.Baker), sulfuric acid (95 %, VWR), sodium hydroxide pellets (Merck), ammonium hydroxide (25 %, J.T. Baker).

4.2. Mechanocatalytical pretreatment

The acid catalyst (2 mmol per gram straw) was dissolved in 150 mL diethyl ether. 10 g of barley straw sample was added to the acid solution and kept for 30 min shaking at room temperature (Stuart orbital incubator S1500, 170 rpm). The solvent was removed using a vacuum rotary evaporator (Heidolph Laborota 4010 digital, 40 C). Dry acid-impregnated straw (2.4 g) was applied to a stainless steel container (45 mL, 16 milling balls each 2.93 g and 1 cm in diameter) and grinded in a ball mill (Fritsch premium line Pulverisette 7) at 800 rpm. The grinding time was set at 1 h including 12 cycles of 5 min grinding and a break time of 10 min in order to avoid overheating and burning of the sample. The temperature was controlled manually after every run (TM-903 LT Lutron).
4.3. Acid-catalyzed hydrolysis

Acid hydrolysis was carried out without any further addition of acid catalyst with the pretreated barley straw. Pretreated straw samples of 5 wt.% in distilled water were hydrolyzed for 1 h either by shaking at room temperature (RT) or by heating in an oil bath at 100°C. The hydrolysis causes the formation of a precipitate which is separated from the sugar solution by filtration. Additionally, direct hydrolysis of the non-impregnated straw has been performed by adding the acid catalyst directly to the 5 wt.% suspension without prior impregnation and mechanical pretreatment.

4.4. Alkali hydrolysis

Alkali hydrolysis was carried out with either 1 M sodium hydroxide (2 mL) or 25 % ammonium hydroxide in a 5 wt.% sample suspension with a total volume of 10 mL. The samples were hydrolyzed for 1 h either by shaking at room temperature (RT) or by heating in an oil bath at 100°C. Additionally, direct hydrolysis of unmodified straw has been performed by adding the base catalyst directly to the 5 wt.% suspension without prior impregnation and mechanical pretreatment.

4.5. Analytical methods

4.5.1. Determination of acid loading by titration

Acid loading of the impregnate was determined by titration. 1 g of straw impregnate was suspended in 40 mL of distilled water and titrated with 0.01 M and 0.1 M NaOH for organic acid-impregnated and sulfuric acid-impregnated straw, respectively.

4.5.2. Elemental and structural analysis

The total carbon content (TC) of the dry straw sample was determined by elemental analysis with a Perkin Elmer CHNS analyzer. Structural analysis of the raw materials were carried out by Fourier-transformed infrared spectrometry (FT-IR) which provided detailed information on the chemical bonds in the molecules.

4.5.3. Determination of Total Reducing Sugar by UV/ VIS spectrometry

The amount of total reducing sugar (TRS) was determined according to the DNS (dinitrosalicylic acid) method using a Shimadzu UV-1800 spectrometer [13]. The measurement provides fast TRS analysis which allows an estimation of the sugar concentration. The reaction is based on a simultaneous oxidation of functional sugar groups, accompanied with the reduction reaction of the DNS reagent. A color change from light yellow to orange, brownish or reddish-brown occurs depending on the amount of fermentable sugars. A (diluted) portion of the hydrolyzed biomass filtrate was mixed with a 1 % 3.5-dinitrosalicylic acid reagent in a volume ratio of 1:1 and subsequently heated in a boiling water bath for 5 min. The TRS was determined at a wavelength of 540 nm based on a glucose calibration. The analysis was carried out in triplicates.
4.5.4. Capillary electrophoresis

The hydrolysates were filtered with a 0.45 µm GHP Acrodisc syringe filter and diluted with water. CE analyses were performed with a P/ACE MDQ CE instrument (Beckman-Coulter, Fullerton, CA, USA) equipped with a diode array detector (DAD), using a modified method of Rovio et al. (2007) [14]. Uncoated fused-silica capillaries of I.D. 25 µm and length 30/40 cm (effective length/total length) were used. The samples were injected at a pressure of 0.5 psi for 10 s and the separation voltage was +16 kV. Calibration curves for the external quantification of HMF, sucrose, lactose, cellobiose, galactose, glucose, mannose, arabinose and xylose. All samples were measured as duplicates. In addition, each sample run was performed with spiked standards to confirm the identity of the analytes.
