### ABSTRACT

The optimization of photovoltaic (PV) solar power plants location in Atacama Desert, Chile, is presented in this study. The study considers three objectives: 1) Find sites with the highest solar energy potential, 2) determine sites with the least impact on the environment, and 3) locate the areas which produce small social impact. To solve this task, multi-criteria decision analyzes (MCDA) such as analytical hierarchy process (AHP) and ordered weighted averaging (OWA) were applied in a GIS environment. In addition, survey results of social impacts were analyzed and included into the decision-making process, including landscape values. The most suitable sites for solar energy projects were found near roads and power lines throughout the study area. Large suitable areas were found also from central valley from Arica and Parinacota to the north edge of Atacama region. In Atacama region, most suitable sites were found in the Andes. On the contrary, Andes were also found to have high environmental values and scenically valuable landscapes. Moderate and low suitability were found on the coast, especially in Atacama region. Factors such as slope and distance to power lines and roads influenced largely the sensitivity analysis. Area of high suitability increased by 15% when distance to roads was excluded and 18% when distance to power lines or slope was removed. MCDA-GIS method was found to be useful and applicable to the optimization of solar power plant locations in northern Chile.

**KEYWORDS:** AHP\_OWA -method, GIS, Multi-criteria decision analyze, Northern Chile, Photovoltaic solar power plants, Site selection

## 30           1.     **INTRODUCTION**

31 Fossil fuels consumption has been increasing (Yonca Aydin et al. 2010) despite of the Paris Agreement to the  
32 United Nations framework convention on climate change (United Nations 2015). Maintaining the economic  
33 development without neglecting environmental issues has turned the focus of policies of several countries towards  
34 renewable energy systems (RES) (Yonca Aydin et al. 2010). Solar energy systems are air pollution free during  
35 their maintenance phase, and therefore, considered environmentally friendly forms to produce energy (Wang and  
36 Qiu 2009). Solar energy is an advantageous option especially in arid areas where solar energy potential is high  
37 (Moriarty and Honnery 2012). Phovoltaic (PV) solar power plants, especially so-called thin film panels, have  
38 gained popularity because the solar panels have recently become more affordable (Hosenuzzaman et al. 2015).

39 Sustainable energy as a part of sustainable development is defined as equality of providing energy to all people  
40 and protection of environment to the next generations (Omer 2008). Renewable energies have been approved to  
41 be sustainable. Nevertheless, there are still considerations related to the RES installation (Nguyen 2007; Yonca  
42 Aydin et al. 2010). RES have positive impacts such as mitigation of the effects of greenhouse gases (Alsema 2000;  
43 Shafiee and Topal 2009). Relevant negative environmental impacts of solar power plants are caused by the  
44 construction phase of panel areas when soil is removed and altered (Tsoutsos et al. 2005). Removal of the soil  
45 destroys biological crust (Johansen and Clair 1986) and local flora and fauna (Wu et al. 2014). In addition,  
46 maintenance phase of PV plants has ecological impacts such as habitat fragmentation, breaking of ecological  
47 corridors, and loss of habitats. Panels also alter microclimate that causes biota conditions to change, resulting in,  
48 for example, changes in species' abundances and/or compositions (Tsoutsos et al. 2005; Wu et al. 2014; Suuronen  
49 et al. 2017). Therefore, environmental and ecological impacts should be considered when planning PV plant  
50 projects.

51 Studies of biodiversity loss, climate change, etc. have proved that environmental problems cannot be solved only  
52 as environmental problems, but also social studies related to them are needed (Binder et al. 2013). Literature  
53 reveals that environmental and economic factors of landscape have been analyzed more profoundly than social  
54 factors (Parsons and Daniel 2002; Tolli et al. 2016). Tools to measure social factors are not fast and effective  
55 because opinions are hard to measure and analyze (Daniel 2001; Sevenant and Antrop 2009). Therefore, social  
56 factors are often left with less attention (Olson-Hazbourn et al. 2016; Tolli et al. 2016). Literature identifies that  
57 the most important social impacts of solar energy are public acceptance, job creation, and social benefits such as  
58 progress of the region, income, health benefits, etc. (Wang et al. 2009). In addition, public support to solar power

59 plants is not only due to environmental benefits, but also related to economical beliefs and landscape impacts  
60 (Olson-Hazbourn et al. 2016).

61 Optimal site selection for PV solar plants requires multidisciplinary data. Nevertheless, not all disciplines support  
62 the selection of the same geographical sites (Malczewski 1999). For example, energy potential of some area can  
63 be high but the area can possess high biodiversity value, and therefore, it is not suitable for PV solar plant projects.  
64 While working with spatial information, geographic information systems (GIS), such as ArcGIS (ESRI, Redlands,  
65 CA) are commonly used (Carver 1991; Arán Carrión et al. 2008; Yonca Aydin et al. 2010; Charabi and Gastli  
66 2011; Uyan 2013; Watson and Hudson 2015; among others). Complex databases need to be organized and  
67 managed with multi-criteria decision analysis (MCDA) techniques if taking several partly conflicting criteria into  
68 account (Malczewski and Rinner 2015). GIS and MCDA are commonly combined (GIS-MCDA) and often used  
69 during the recent years (Malczewski and Rinner 2015). MCDA with Saaty's (1997) analytic hierarchy process  
70 (AHP) has been demonstrated to be useful in the site selection of grid-connected solar power plant projects (Arán  
71 Carrión et al. 2008). MCDA combined with ordered weighted averaging (OWA) is even more powerful decision-  
72 making tool (Yager 1988; Boroushaki and Malczewski 2008). OWA includes into the calculations how many of  
73 the criteria should be accomplished to reach a satisfactory level of all criteria (Yager 1988). Combined method of  
74 AHP\_OWA is an effective tool in decision-making because it is more flexible than AHP alone (Boroushaki and  
75 Malczewski 2008). AHP alone is a robust method (Charabi and Gastli 2011; Jamali et al. 2014) and OWA allows  
76 the user to define the amount of acceptable uncertainty in the process (Malczewski 2006). By utilizing spatial  
77 information and by recognizing the consequences of PV power plants, governmental decision-making and site  
78 selection can be supported and the loss of cultural heritage, ecosystem services, biodiversity, and whole  
79 ecosystems can be avoided.

80 AHP\_OWA has been used in multiple cases of MCDA (Hokkanen and Salminen 1997; Bell et al. 2011; Joerin et  
81 al. 2001; Drobnik et al. 2017). AHP is commonly used to solve multi criteria problems of renewable energy  
82 (Chatzimouratidis and Pilavachi 2009; Sánchez-Lozano et al. 2013; Uyan 2013; Watson and Hudson 2015), but  
83 only a few articles include OWA as part of MCDA method of solar power plants site selection (Charabi and Gastli  
84 2011). In addition, social effects are poorly represented in these studies. Social factors such as aesthetics (Yonca  
85 Aydin et al. 2010) and landscape values (Bergmann et al. 2006; Chiabrande et al. 2011; Molina-Ruiz et al. 2011;  
86 Pasqualetti 2011) are sometimes included in the MCDA processes. Wide MCDA studies include social factors of  
87 renewable energy such as job creation (Kosenius and Ollikainen 2013; Ahmad and Tahar 2014), public acceptance

88 (Wüstenhagen et al. 2007; Amer and Daim 2011; Ahmad and Tahar 2014), and distances to historical sites and  
89 cities (Sánchez-Lozano et al. 2013; Watson and Hudson 2015).

90 On one hand, studies are focused on numerous factors of energy efficiency and solar energy potential as well as  
91 on economical facts (Charabi and Gastli 2011), but on the other hand, multiple surveys of renewable energy  
92 attitudes exist (Krohn and Damborg 1999; Kaldellis 2005; Sardanou and Genoudi 2013; Ek and Persson 2014;  
93 Olson-Hazbourn et al. 2016; among others). Nevertheless, according to our knowledge, surveys have not been  
94 applied in GIS environment together with physical and environmental factors of solar power plants.

95 The present study identifies optimal areas for PV solar energy projects, along with multiple aspects of sustainable  
96 energy, including social factors in a form of survey results as GIS layers. Three aspects, solar energy potential,  
97 environmental facts, and social characteristics were considered. Suitable locations for PV solar energy projects  
98 were determined using spatial information of northern Chile. AHP\_OWA was used in the MCDA process to  
99 resolve the most suitable areas. Finally, the individual result layers were combined by using weighted summing.

## 100 **2. MATERIAL AND METHODS**

### 101 **2.1. Study area**

102 Study area includes four regions of Northern Chile (Fig. 1): Arica and Parinacota (XIV), Tarapacá (I), Antofagasta  
103 (II), and Atacama (III). These regions receive scarce precipitation mainly in the Andes and as coastal fogs in the  
104 coast (Moreira-Muñoz 2011). Opposite to the coastal area, inland has the world's driest desert, the Atacama  
105 Desert. Vegetation in the study area varies from non-vegetated true deserts to grasslands and scrubs, and contains  
106 small areas of forests (Pliscoff and Luebert 2006). Cities are mainly in the coastal area or situated close to mines.  
107 Agricultural land can be found in river valleys where water is available.

108  
 109 **Fig. 1.** Chile is on the Pacific Ocean side of South America shown on the right. Study area is situated on four  
 110 regions shown with grey color in the main map and enlarged on the left. Focus area used in sensitivity analysis is  
 111 indicated with grey color in Atacama region shown in the regional map at bottom left.

## 112 2.2. Methods

113 Site selection of PV plants was carried out using the multi-criteria decision-support system. The study had one  
 114 goal: Locate optimal sites for PV plants in northern Chile considering social and environmental aspects of  
 115 sustainable development. The goal was reached through three objectives: 1. Determine high solar energy potential  
 116 sites with economically reasonable distances to roads and power lines. 2. Exclude areas of conservation and/or  
 117 high biodiversity from optimal sites and prevent vegetation loss. 3. Consider the social impacts and find socially  
 118 acceptable sites. Downloadable georeferenced data were used to analyze the three objectives. In addition, a survey  
 119 was used in decision-making to characterize the chosen social aspects given below. Pretreatment of the  
 120 georeferenced data was done with ArcGIS ® v10.1. (ESRI, Redlands, CA) and all MCDA-related data analyzes  
 121 were performed with TerrSet® v18.20.

122 Objectives were characterized through three criteria: physical, environmental, and social (Table 1). Criteria were  
123 divided into factors (Table 1). Physical criteria were divided into 5 continuous factors: Average temperature  
124 (temperature hereafter), global irradiation, orography (i.e. slope and orientation), distance to power lines, and  
125 highway accessibility (i.e. distance to power lines). Environmental factors were divided into 2 continuous factors  
126 (biomass, vegetation type rarity), and one categorical factor (land use). Social factors were divided into two  
127 continuous factors (distance from the closest city and biomass), and one categorical factor (visibility from the  
128 roads) (see reasoning for the factors: “Defining decision rules”).

129 Constraints of the site selection were defined with binary values, 0 as non-suitable site and 1 as suitable (Table  
130 2). Environmental factors had several constraints including protected terrestrial and aquatic sites (Table 2). Social  
131 aspects had two constraints: visibility from historical sites and from typical zones. Typical zones were areas  
132 including cultural environment and traditional landscapes that are categorized as valuable to conserve by the  
133 Ministry of Public Education of Chile (2010). No solar power plants were allowed to be visible inside the 10-km  
134 radius from historical sites or typical zones. The continuous and categorical factors are given in Table 1 and the  
135 constraints in Table 2.

136 Continuous factors were standardized directly with fuzzy sets, by converting them into value range 0-255 (Table  
137 1), because using 8-bit (one byte) values makes the MCE calculations in TerrSet faster (Eastman 2015). In our  
138 case, value 0 indicates the least suitable and 255 the most suitable locations. Fuzzy sets are functions that change  
139 the values from non-membership to membership class smoothly so that sharp boundaries are not created (Eastman  
140 2016). Categorized factors were given relative importance values (Jamali et al. 2014) with expert judgement,  
141 before they were standardized with fuzzy sets (Table 1). Land use classes were given values from 1 to 4 according  
142 to the lands’ former introduction to anthropogenic use (Table 1). When giving the weights to land use  
143 anthropogenic affected sites (i.e. urbanized, cultivated, and mosaics) were weighted to be more suitable areas than  
144 sites at their natural state (i.e. shrubs, herbaceous coverage, and forests). Visibility was given values either 1 or 2  
145 according to 10-km radius (Table 1). Afterwards all factor levels were compared pair-wise and relative importance  
146 weights (RIWs) were calculated (Saaty 1997) (Table 3, Fig. 2). OWA-method (Yager 1988; Boroushaki and  
147 Malczewski 2008) was applied to all three aspects (environmental, social, and physical) (Table 4, Fig. 2). The  
148 final map was calculated with equal AHP-weights (0.333) and with weighted linear combination (WLC) to  
149 combine the conflicting suitability maps of criteria to find the best sites (Table 5, Fig. 2). Equal weights and WLC  
150 was used to obtain equality between the three aspects, because WLC aloud free tradeoff between the aspects. Each  
151 one of the aspects reaching high suitability values at certain pixel can be fully tradeoff with another aspect in

152 WLC. Therefore, the optimal areas of all tree aspects can be presented equally in a final map. Finally, a sensitivity  
 153 analysis was done by performing factor removal (Malczewski and Rinner 2015). All factors were first given equal  
 154 weights and then one factor at a time were taken off from the analysis to see the effect of that single factor, and to  
 155 enable the calculation of change in the amount of suitable areas (Malczewski and Rinner 2015).

156

157

158 **Fig. 2.** Work flow for location optimization of PV solar power plants. After identification and collection of the  
 159 data, a) factors were standardized with fuzzy sets and their relevancy order was evaluated, then b) environmental  
 160 and social constraints were defined and survey of social factors where applied to define the AHP weights of social  
 161 factors. Next, c) physical and environmental factors were given AHP values according to literature and expert  
 162 judgement. After AHP weighting, d) factors were given to tradeoff with OWA -method. For the final map, e)  
 163 equal AHP and OWA weights were used.

164 Table 1. Criteria and categorical factors used in the AHP\_OWA method. Mo. stands for “monotonically”.

Criteria	Factor	Fuzzy membership (Eastman 2015)		Class range / description	Motivation	Source (Additional information)

178

179 2.3. Defining decision rules

180 2.3.1. Rules for physical criteria

181 Solar energy potential maps have already been created in Chile (Escobar et al. 2014; Ministry of Energy, Chile  
182 2013). Despite of the importance of environmental and social criteria to sustainable site selection, physical solar  
183 energy potential still is the prime criterion. If sufficient solar energy potential is not reached, the installation of a  
184 new panel area is not reasonable (Borouhaki and Malczewski 2008). Physical factors were given importance  
185 weights in the following order: temperature, global irradiation, orography (slope, then orientation), highway  
186 accessibility and distance to power lines (Arán Carrión et al. 2008). Distance to power lines is not considered  
187 important, because the present study considers multiple purposes of local PV plant projects, which are not  
188 necessarily grid connected. Nevertheless, close distance to power lines gives an opportunity to connect the solar  
189 plant to grid when desired. Given the high potential of solar energy in northern Chile, risk of getting insufficient  
190 amount of solar radiation is small. Therefore, some tradeoff between the physical factor and intermediate risk with  
191 OWA weights was used.

192 2.3.2. Rules for environmental criteria

193 Considering the environmental criteria, water and vegetation are scarce in northern Chile. Therefore, they are the  
194 most important environmental factors and they were given 100 m buffer area to protect them. This distance was  
195 chosen based on Arán-Carrión et al. (2008). Areas with high biodiversity like national parks, private protected  
196 areas, nationally protected wetlands, etc. were considered as constraints (Table 2). Because environmental aspects  
197 are also closely related to social aspects (Liu et al. 2007), conserving water bodies, natural parks, and biodiversity

198 may also maintain the welfare of the people and protect their sources of livelihood. Therefore, the constraints in  
199 the present study included also social characteristics.

200 Other considered environmental factors were intensity of land use, biomass, and vegetation type rarity. Land use  
201 was considered to have the highest weight and biomass the second highest (Table 2). In fact, agricultural fields  
202 have the highest biomass values in the study area, but they do not necessarily possess high endemic biodiversity.  
203 On the other hand, agricultural land has a high value for human wellbeing. Therefore, land use was given the  
204 highest value. Vegetation type rarity was important because desert vegetation may be scarce, and therefore, not  
205 always characterized properly by the amount of biomass. Some tradeoff between environmental factors was  
206 allowed in OWA because the factors could compensate each other to some extent. For example, high biomass  
207 areas could be sacrificed if the current land use was agriculture.

### 208 2.3.3. Rules for social criteria

209 Landscape around historical monuments and culturally important zones (i.e. typical zones) were ruled out from  
210 site selection by constraints because those areas possess a high cultural heritage. Visibility from the roads was  
211 given less value for suitability, if landscape value (i.e. active volcanos, hills with slope over 15 % steep, high  
212 biodiversity sites, etc.) was expected to exist. According to Molina-Ruiz et al. (2011) 10-km visibility radius has  
213 the strongest visual impact to the viewer and, therefore, this constraint was chosen to the present study.

214 Social impact is known to be higher depending on how many people are affected by renewable energy installations  
215 (Fernandez Jimenez et al. 2015). More people will be affected by the visual effects of PV plants if they are seen  
216 from the cities than if they are seen from the roads. Therefore, highest weight was given to distance from the cities  
217 -factor and then visibility from the roads. If solar power plants would be right outside the city, social impacts  
218 would be strong. For example, movability from and in the city, would be affected because people must go around  
219 the power plant area (Tolli et al. 2006). Social factors were allowed to tradeoff (OWA) because of the uncertainty  
220 of the concern-based factors. Social factors decision rules were defined through distances from cities, 10-km  
221 radius non-visibility from the historical sites and typical zones, and applications from survey as described below.

## 222 2.4. Spatial referenced data

### 223 2.4.1. Obtaining data

224 Shapefiles of Chile such as regions, roads, vegetation, temperature, cities, and thematic maps (Tables 2 and 3)  
225 were downloaded from the webpages: IDE (2016), SINiA<sub>BETA</sub> (2016) and Albers (2012). Landscape values and  
226 environmental regulations were obtained from SEIA (2013). Two power line systems, found in northern Chile,

227 Central Interconnected System and Interconnected System of Norte Grande were obtained as point shapefiles  
228 from the National Power System Coordinator, Chile (2016). Landsat 5 Thematic Mapper (2011) images were  
229 downloaded from the U.S. Geological survey (USGS). The most accurate data, such as DEM and Landsat 5 TM  
230 (2011), had a resolution of 30 x 30 m. Global irradiation data was 500 x 500 m (Ministry of Energy, Chile 2013),  
231 and temperature had the lowest resolution of 4000 x 4000 m (Albers 2012). Global irradiation data did not contain  
232 the region Arica and Parinacota, and parts of mountainous regions. Global irradiation data were filled with less  
233 accurate data where the Weather Research and Forecasting model (WRF) was used from the same source. Raster  
234 data (elevation and satellite pictures) were downloaded from USGS. ASTER GLOBAL DEM with 1 arc second  
235 resolution was used to calculate slope and orientation. All data were converted into raster format for the analyzes  
236 using a raster size of 60 x 60 m (Fig. 3 a).

#### 237 2.4.2. Application of physical criteria

238 Missing global irradiation data in Parinacota and Arica was filled with lower quality irradiation data (WRF,  
239 Ministry of Energy, Chile 2013) (Fig. 3 b). Both Global irradiation and temperature data were interpolated with  
240 kriging method using trend removal with second (global irradiation) and third (temperature) order polynomial  
241 surfaces. DEM was converted from angular to linear metric units (resampled to 60 x 60 m). Two additional  
242 distance layers were created indicating the distances from each raster cell center to the closest road and to the  
243 closest power line. These distances were obtained by converting raster cell locations into points and by performing  
244 spatial joining of roads and power lines to them (Fig. 3 c). DEM was also used to create slope and orientation data  
245 (Fig. 3 d).

#### 246 2.4.3. Application of environmental criteria

247 Vegetation type rarity was calculated from Pliscoff and Lueberts' (2006) 40 vegetation zones found in the study  
248 area. One big ecosystem is better for the organisms than several small ones although the total surface area would  
249 be of the same size (Margules and Pressey 2000). Therefore, different vegetation types were given a numeric  
250 value by dividing the total surface area of the vegetation type with the amount of separate areas of certain  
251 vegetation type (Fig. 3 a). Vegetation zones with small surface areas were given lower suitability values than large  
252 vegetation zones. Land use was given values as described above (Fig. 3 a)

253 Rain falls to the Atacama Desert depending on El Niño Southern Oscillation (ENSO) (Troup 1965; Rasmusson  
254 and Wallace 1983; Vargas et al. 2000). It is an irregular oscillation in the Pacific Ocean, which changes wind and  
255 water temperatures. "El Niño" phenomenon brings warmer waters to the coast and more evaporation, which can

256 lead to rains over the Atacama Desert (Aceituno and Montecinos 1993; Vargas et al. 2000; Houston 2006). Rain  
257 falls typically between May and August (Aceituno and Montecinos 1993; Muñoz-Schick et al. 2001; Houston  
258 2006) and vegetation starts to bloom one month after the rain (Vidiella et al. 1999). Year 2011 was a typical “El  
259 Niño” year and, therefore, Landsat 5 TM data from August to November 2011 was used (Fig. 3 e). Landsat 5  
260 Thematic Mapper was used to calculate normalized difference vegetation index (NDVI) (Rouse et al. 1974) (Fig  
261 3 e). While mosaicking, NDVI maps resolution was set to 60 x 60 m.

#### 262 2.4.4. Application of social criteria

263 Survey (Fig. 3 f) included concerns of possible environmental impacts of PV solar power plants and it was  
264 performed during 2014-2015 in Chile. Survey had 444 participants including professionals and students of  
265 engineering (14%) and environmentalist (22%). Survey was given to the students at four different universities and  
266 spread through professional networks of engineers and environmentalist. Also non-professional people were  
267 randomly asked to participate to the survey in several towns from Iquique to Concepción (64%). Engineers were  
268 working or studying electronics, civil engineering, mechanics, etc. and the environmentalists were biologists,  
269 agronomists, geographers, or environmental or forestry engineers. Questions were answered using a Likert’s scale.  
270 Public acceptance with scale: 1 = I haven’t thought about it, 2 = Not concerned at all, 3 = Little concerned, 4 =  
271 Quite concerned, 5 = Very concerned (Fig. 4). Explorative factor analysis (Thurstone 1935) was performed to  
272 group the questions. Cronbach’s alpha (Cronbach 1951) was calculated before and after doing the factor analysis,  
273 and the factor analysis grouping of variables was accepted if the alpha was improved or maintained the same  
274 value. For the higher concern areas, smaller suitability values were given. Three most important potential concerns  
275 in the survey were considered as important concerns (Fig. 4): loss of flora and fauna, loss of scenic landscape, and  
276 increase of groundwater uptake for the cleaning of the panels. AHP weights were given in the order presented  
277 above and in Table 3.

278 Concerns over loss of flora and fauna were included into the study by preferring low biodiversity areas. Therefore,  
279 NDVI layer was used again in this context, as “vegetation value”, but values were recalculated using the weights  
280 of social factors. In addition, human health is associated with ecosystems health (Tzoulas et al. 2007), and  
281 ecosystem services affect positively to human well-being (MEA 2005). Landscape was also considered important  
282 to be maintained and that was included in the visibility considerations. Since 10 km is considered as high visibility  
283 impact area (Molina-Ruiz et al. 2011), landscape values from the roads were considered with the same visibility  
284 radius, and were determined using the Viewshed tool of ArcGIS (Fig. 3 f). Visibility results from the roads, cities,  
285 and historical and natural monuments were calculated with ArcGIS Viewshed tool using digital elevation data

286 (DEM). Areas with potential mountain landscape value, where there was a slope of 15 % or more and with an  
 287 area of at least 500 x 500 m, were also defined, but it is not known if those areas are considered to have scenic  
 288 value. Distances from these slopes were defined a 10-km radius and extracted by masking the result with the  
 289 visibility layer to find those hillsides which can be seen from the roads. Areas with high biodiversity, water bodies,  
 290 protected areas, etc. were also included in the high visibility impact area. The visibility layer was edited manually,  
 291 by clipping out the 10-km radius buffer where landscape value targets were not found. Finally, to keep the social  
 292 impacts small, proper distance for solar power plants from the large cities was defined to be over 5 km (Arán  
 293 Carrión et al. 2008), and under the 5-km suitability decreased rapidly. Spatial joining was used to define the  
 294 distances from the cities (Fig. 3 d).

295

296

297 **Fig. 3.** Data modification of the factors: a) Shapefiles were converted to raster and given numerical values and  
 298 survey gave the motivation for the landscape values, b) two global irradiation data were joined, c) distance to the  
 299 roads and power lines, and distance from the cities were calculated with spatial joining using DEM cell center  
 300 based points, d) slope and orientation were calculated from the DEM, e) biomass was calculated using NDVI, and

301 f) shapefiles visibility layer was created identifying areas inside the 10 km from the roads containing landscape  
 302 value. Created layers (i.e. factors) are indicated with bold letters.

303

304

305 **Fig. 4.** Average concern answers of potential environmental impact of PV plants. Abbreviation Acc. stands for  
 306 accumulation.

### 307 **3. RESULTS AND DISCUSSION**

308 Created map is an overall view of the larger area and cannot substitute environmental impact assessments of  
 309 specific areas done with field work. Especially smaller important habitats of rare species cannot be found from  
 310 low-resolution satellite images, and therefore, are not shown on the resulting map.

311 Used OWA-method, with low risk and some tradeoff, can be over cautious considering that solar energy potential  
 312 is abundant in the whole study area. Therefore, the most suitable areas in the present study are highly suitable.  
 313 Allowing more tradeoff between the factors would make the estimated suitability more uncertain. Map  
 314 demonstrated large areas with high suitability for PV plant projects. Highest suitability areas were found alongside  
 315 roads and power lines in Antofagasta region. In addition, suitability grew higher towards the Andes in Atacama  
 316 region (Fig. 5). In fact, absolute desert in the central valley in Antofagasta, Tarapacá, and Arica and Parinacota  
 317 areas are highly suitable for solar power plant projects. In Atacama region, Andean area is more suitable than the  
 318 coastal region (Fig. 5) because of high biodiversity values and lower solar radiation potential of the coast.

319 Conflicting to high suitability at the Andes, mountainous areas were also defined having a high landscape value  
320 (Fig. 5).

321 Solar radiation is one of highest in the world in the study area (Corral et al. 2012; Jiménez-Estévez et al. 2015;  
322 Salazar et al. 2015). Nevertheless, suitability in the central valley is decreased by temperature (Fig. 5). Elevated  
323 temperatures lower the energy efficiency of solar panels (Dubey et al. 2013). For example, reduction of  
324 temperature by 3–9 °C, the electrical performance improves so that the same amount of energy can be produced  
325 with 2 m<sup>2</sup> smaller panel surface area (Dubey et al. 2013). Therefore, even the lowest values of global irradiation,  
326 3.89 kWh/m<sup>2</sup>/day, can be suitable for solar power plant projects if temperatures are lower. The Atacama Desert  
327 in northern Chile has one of the highest solar radiation potential in the world (Corral et al. 2012; Jiménez-Estévez  
328 et al. 2015; Salazar et al. 2015). Solar irradiation of northern Chile is between 3.89 – 7.80 kWh / m<sup>2</sup> / day, while  
329 similar studies reported 3.89 – 5.56 kWh / m<sup>2</sup> / day in Turkey (Uyan 2013) and 4.56 – 4.91 in Spain (Arán Carrión  
330 et al. 2008). Therefore, the Atacama Desert is an ideal location to install solar energy if only the solar energy  
331 potential is considered.

332 Even though the solar energy potential is high in some remote places, they are not reasonable places for  
333 installations, if there is no energy-demanding infrastructure nearby. However, these places can be attractive to  
334 local mines, which are abundant in the Andean region. Lowest priority was given to the distance to power lines  
335 and roads, but they are also clearly seen as higher score areas because other factors are high in those areas as well.

336 According to Gottschamer and Zhang (2016) environmental, technological, societal, policies, and economic  
337 factors should all be considered in RES projects, because they are all connected. In the present study, connection  
338 between social and environmental factors were clearly seen. Landscape values and amount of biomass had  
339 characteristics that were categorized in environmental and in social aspects. In contrast, survey results were not  
340 straightforward to interpret. Yonca Aydin et al. (2010) concluded that because solar energy is seen as clean energy,  
341 some people see renewable energy installations as positive. Nevertheless, other people might reject them. In the  
342 present study, people who rejected PV solar plant installations can also be more concerned of possible  
343 environmental or social impacts. Nevertheless, concerns gained by the survey, corresponded with the landscape  
344 values determined by SEIA (2003) national guide of environmental impact assessment.

345 Compared to other GIS-based MCDA studies (Arán Carrión et al. 2008; Yonca Aydin et al. 2010; Uyan 2013;  
346 Watson and Hudson 2015; among others), the method used here gave less suitability values to vegetated areas  
347 because vegetation is included as an index and because it has both cultural and environmental values. Areas with

348 possible landscape value are also defined here. For example, many mountainous roadsides show lower suitability  
349 (Fig. 5). Map predicts possible landscape value areas, which should be confirmed in the field. In fact, it is not  
350 known if these areas contain aesthetic values because of the physical area described above in application of social  
351 factors.

352 Absolute desert in the central valley from Arica and Parinacota to the northern part of Atacama region shows high  
353 suitability values also due to the land use and low NDVI values (Fig. 5). The coastal area, especially in Atacama  
354 region, shows low suitability values (Fig. 5). Coastal areas have fogs, which bring humidity to them, and therefore,  
355 possess higher amounts of biomass. Fogs decrease solar energy potential received by the ground and lower  
356 suitability further (Fig. 5). Cultivated areas have monocultures of grapes, but they do possess endemic vegetation  
357 as well. Nevertheless, they have higher suitability for PV plant projects than the surrounding mountains, because  
358 cultivated areas are highly modified compared to natural sites (Fig. 5).

359

360

361 **Fig. 5.** Final map including physical, environmental, and social aspects of optimal site selection. Natural breaks  
 362 were used to classify the suitability areas into five classes given in the legend in ArcGIS.

### 363 3.1. Sensitivity analysis

364 Sensitivity analyses were conducted for all factors, and in each of them one factor was removed (Fig. 6). Removal  
 365 of factors slope, distance to roads, and distance to power lines, increased the area of very high suitability (Table  
 366 6) indicating that these factors defined where the very high suitability areas are (Fig. 6 d, f, g, j and l). Therefore,  
 367 they are highly important qualities when creating suitability map for PV solar power plants. Removal of  
 368 temperature, global irradiation, or biomass caused low suitability area to increase, while high suitability classes

369 decreased (Table 6). This means that more area was suitable for PV plant installations when these factors were  
 370 included in the analyzes.

371

372

373 **Fig. 6.** Suitability maps showing changes caused by factor removal method. First map was obtained with a) all  
 374 factors and equal weights, and then b)–l) show results obtained by removal of each factor. The maps are showing  
 375 the focus area, Valley of Copiapó in the Atacama region. Constraint on the left side of focus area is “desierto  
 376 florido” and on the right middle “Quebrada de Serna”. River Copiapó with 50 meters buffer runs from the South  
 377 East to the North West direction. Natural breaks method in ArcGIS was used to classify suitability.

378

379 **Table 6.** Factor removal sensitivity analysis showing changes caused by individual factors calculated as  
 380 percentages compared to equally weighted all-factors-included situation.

Factor removed	Low		Moderate		High		Very high	
	km <sup>2</sup>	%	km <sup>2</sup>	%	km <sup>2</sup>	%	km <sup>2</sup>	%
Temperature	13428	16	-1870	-2	-10535	-12	-1031	-1

381

#### 382 4. CONCLUSIONS

383 Combined AHP\_OWA method applied here was found useful for preplanning of PV plant projects in northern  
 384 Chile. The present study does a comprehensive study of the whole northern Chile, but more local analyzes with  
 385 detailed information is encouraged. Method presented here, can be applied in any region of the world when  
 386 planning PV power plant locations if the same kind of data is available for the site. Method is most suitable to  
 387 deserts because water and natural vegetation were used as constraints.

388 Social impacts and locals' opinions should be included in the decision-making processes. Nevertheless, care  
 389 should be taken when evaluating social factors and displaying them on a map, because opinions are hard to  
 390 interpret. In fact, opinions differ among people and overall opinions can include conflicts. In addition, cultural  
 391 and environmental aspects are not always separable into two distinct categories of factors. Including social aspects  
 392 to PV solar plants site selection planning, conflicting sites, such as high energy potential areas with high  
 393 vegetation, can be detected. Therefore, possible conflicts between human welfare and solar energy projects can  
 394 be avoided. In the future, if available data exists, lands of the indigenous peoples should be added to spatial  
 395 decision-making studies.
