Abstract

The thermochemical behavior of cellulose, glucomannan, and xylan was investigated by pyrolysis–gas chromatography–mass spectrometry (Py-GC/MS). In each case, major GC-amenable condensable products were classified into several compound groups, and the formation of these monomer-related fragments from the model substance samples was determined at 500, 600, and 700 °C with a residence time of 5 s and 20 s. The results revealed that despite some general formation trends, no compound group was selectively formed at certain temperatures. Of the 11 product groups, the primary ones, including lactone, furan, and cyclopentenone derivatives, accounted for 72–85% (from cellulose), 86–90% (from glucomannan), and 76–81% (from xylan) of the total amount of pyrolysis products determined. At 500 °C, about half of the major product groups accounted for lactones, such as 3-hydroxy-2-penteno-1,5-lactone and 5*H*-furan-2-one. It was also confirmed by thermogravimetric analyses that within the temperature range studied, cellulose was thermally more stable than the heterogeneous hemicelluloses. These kinds of data are of importance, for example, with respect to efforts to develop new biorefinery possibilities for renewable resources.

Keywords Cellulose · Glucomannan · Xylan · Pyrolysis–gas chromatography · Condensable products · Thermogravimetry

Introduction

The biorefinery concept can be defined merely as a process for fractionating and/or converting into energy carbon dioxide-neutral feedstock (biomass) as well as a great variety of chemicals and other biomaterials in an ecosystem-friendly way through advanced technologies [1, 2]. The pulp industry, as an essential branch of global industry, is based on vast and multidisciplinary technology. For example, a modern chemical pulp mill that employs one fibrous feedstock is capable of manufacturing, besides pulp, several pulping by-products, and it can be considered a rather sophisticated biorefinery. It is also known that the

integration of a hot-water-extraction pre-treatment stage prior to alkaline pulping may offer a feasible possibility, mainly to recover the dissolved carbohydrates-derived material for further utilization by biochemical and chemical technologies [3]. This concept of an integrated forest biorefinery has been investigated under a variety of conditions and from several points of view.

In our earlier papers, we used pyrolysis–gas chromatography/mass spectrometry (Py-GC/MS) for revealing the thermochemical behavior of silver birch [4] and Norway spruce [5] sawdust, as well as non-wood materials, such as okra and miscanthus [6]. In all cases, the effects of pyrolysis conditions on the product distribution were studied. All the materials were investigated as such and after hot-water extraction together with the pulps obtained from these feedstocks by sulfur-free delignification. In each case, major GC-amenable condensable products were determined and classified into several compound groups, characteristically originated from the main structural constituents (cellulose, hemicelluloses, and lignin) of the raw materials. Additionally, the suitability of this analytical pyrolysis method under varying conditions was investigated as a rapid tool for roughly detecting chemical changes that were taking place in the feedstocks during the different treatments performed.

Thermal analysis can be defined as a set of techniques used to describe the physical or chemical changes associated with substances as a function of temperature [7]. The thermal behavior of lignocellulosic materials and their components can be studied in many alternative ways. Py-GC/MS reveals the composition of products and indicates the mechanisms of degradation reactions; it also provides information about the original structure of the samples being studied. In general, many studies indicated that during pyrolysis under an inert atmosphere, biomass converts into low-degree-polymerized products [8–17]. However, there have still been less attention on pyrolysis of glucomannan and xylan as well as their quantification analyses. The dissimilarities in pyrolysis behavior of the main components in lignocellulosic biomass are due to differences in their molecular structures and chemical natures. Therefore, the study of pyrolysis behavior of the main biomass substituents is essential to understand the overall pyrolysis behavior of biomass. In contrast, thermal gravimetric (TG) analysis (i.e., mass change vs. temperature) and differential scanning calorimetry (DSC) (i.e., heat flux vs. temperature) primarily give information concerning the mass loss of a sample over the whole process, the rate of mass loss, and the endothermic and exothermic temperature ranges upon heating. These methods are widely applied techniques, especially for the study of thermal stability of polymers. In practice, it is useful to record the first derivative of the TG curve (i.e., differential thermogravimetry (DTG)) for more clearly detecting small features/boulders as peaks on the curve. Particularly, successful approaches have also been the simultaneous combination of TG methods and spectroscopic techniques. In general, the mass loss of a sample of the TG curve under a certain heating rate and the peak height of the DTG curve are directly related to the temperature during the process and the reaction rate at the corresponding temperature, respectively. Therefore, investigation of samples by TG and DTG is also important due to fluctuations in available data [18–21].

The cellulose content is 40–45% of the wood dry solids and this carbohydrate is a linear homopolysaccharide composed of β -D-glucopyranose moieties linked together by (1→4)-glycosidic bonds (degree of polymerization (DP) 10,000–15,000) [22]. Many degradation mechanisms with varying reaction kinetics of cellulose pyrolysis have been proposed under changing conditions [23–32]. In the generally accepted pyrolysis reactions on heating after gradual depolymerization, mainly by breaking of glycosidic linkages, a great variety of volatile products are simultaneously formed (the prominent primary example is levoglucosan (LG)). This occurs from the initial degradation reactions, including dehydration, rearrangement, and ring-opening of glucose units, followed by the formation of various

unsaturated products from which a highly reactive char can be obtained by condensation.

Hemicelluloses (25–35% of the wood dry solids) are linear low-molar-mass heteropolysaccharides with specific side-groups, and their thermal and chemical stability is generally lower than that of cellulose, presumably due to their lack of crystallinity and lower DP (100–200) [33, 34]. Softwoods and hardwoods (and non-woods) differ not only in the content of total hemicelluloses but also in the percentages of individual hemicellulose constituents; in hardwoods and non-woods, primarily xylan (containing xylose units), and in softwoods, mainly glucomannan (containing mannose and glucose units). In hardwoods, the content of xylan and glucomannan is 20–30% and < 5% of the wood dry solids, respectively, whereas in softwoods, the corresponding contents are 5–10% and 15–20% of the dry wood solids [33]. The thermal degradation reactions of heteropolymeric hemicelluloses are principally similar to those of homopolymeric cellulose, although hemicelluloses reacted more readily than cellulose during heating [13, 18, 34–36]. The differences observed in the degradation rates of various polysaccharides can be explained as being primarily due to the different glycosidic bonds between sugar moieties as well as different DP and crystallinity of cellulose. Of the hemicelluloses, xylan is the least thermally stable because it is more susceptible than glucomannan to degradation of glycosidic bonds and dehydration reactions [37]. In general, the char formation from hemicellulose pyrolysis is slightly higher than that from cellulose [13, 14, 19, 38].

Lignin is an amorphous polymer with a chemical structure that distinctly differs from the polysaccharide constituents of wood and non-wood biomass [33, 39]. It is generally known that lignin decomposes over a wider temperature range compared to cellulose and hemicelluloses, which are less resistant to thermal degradation and rapidly degrade at lower temperatures over narrower temperature ranges [19, 37, 40]. Thus, the stability of lignin, cellulose, and hemicelluloses against heating increases in the order: hemicelluloses > cellulose > lignin.

A wide range of studies has been made for clarifying the pyrolysis characteristics of varying biomasses by different analytical and pilot-scale techniques [11, 40–46]. Typically, it has been assumed that the pyrolysis behavior of biomass is almost the integration of its components (cellulose, hemicelluloses, and lignin) [13, 23], although the cellulosic contribution normally predominates due to the larger proportion of cellulose in lignocellulosic materials. Hence, it can be observed that with the increasing amount of hemicelluloses in the sample mixture of xylan and microcrystalline cellulose, the maximum decomposition rate of hemicelluloses increases while that for cellulose declines [13]. Unlike the cellulose, the interaction between

hemicelluloses and lignin is strong. The presence of hemicelluloses decreases the lignin decomposition temperature and the mass loss rate, whereas the existence of lignin increases the decomposition rate of hemicelluloses.

In our earlier studies, we investigated the thermochemical behavior of differently treated wood and non-wood materials [4–6]. In this comparable study with model substances, firstly, the aim was to further clarify the formation of compound groups under the same pyrolysis conditions as those applied in our previous experiments. Secondly, to verify the formation of main pyrolysis products with respect to their main carbohydrate constituents as well as the effect of the interaction of main carbohydrate constituents in hardwood, softwood, and non-wood on the pyrolysis products. Since carbohydrates are the main components of various biorefinery fractions, we selected for our Py-GC and TG experiments cellulose and hemicelluloses (glucmannan and xylan) and the quantification analyses of GC-detectable pyrolysis products of these samples were reported. The thermochemical behavior of lignin as well as lignin-containing black liquors from alkaline delignification of wood and non-wood fibrous feedstocks will be separately investigated under the analogous conditions in the forthcoming studies.

Experimental

Thermogravimetric analyses

The slow pyrolysis of the selected biomass components was carried out with a Linseis STA PT1600 instrument. For each test, a sample size of 10–15 mg was used in an alumina crucible. A nitrogen flow of 200 mL min⁻¹ was used to create inert environment and to remove the released volatiles. For drying, the furnace temperature was raised from room temperature (≈ 20 °C) to 105 °C at 20 °C min⁻¹ and maintained at that temperature for 30 min to complete the drying of the sample. Then, the TG run was continued with the same dried samples for pyrolysis. The pyrolysis temperature was selected as 700 °C. For pyrolysis, the sample temperature was raised from 105 °C to 700 °C at varied heating rates of 10, 15, and 20 °C min⁻¹ and maintained at that temperature for 40 min to ensure complete pyrolysis. The data generated through TG experiments were further processed with Microsoft Excel and MATLAB[®].

Pyrolysis experiments

The model substances were α -cellulose (Sigma), glucmannan (MB Med. S. r. L.), and oat spelt xylan (Sigma). In each case, about 0.2 mg of model substances was

pyrolyzed in a quartz tube (3.0 cm \times 1.0 mm inner diameter) between quartz wool which was used to keep the solids inside the pyrolysis tube. First, a partly filled quartz tube with quartz wool was cleaned at 1000 °C to remove all adsorbed gases and vapors on the surface of the quartz tube. Then, fast pyrolysis of substances was conducted at a temperature of 500, 600, or 700 °C (heating rate 20 °C ms⁻¹ and heating times 5 and 20 s) using a CDS Pyroprobe 1000 heated filament pyrolyzer coupled to an HP 5890 II gas chromatograph (Py-GC, Hewlett Packard Company, Wilmington, NC, USA).

The GC conditions were the same as those applied earlier to the similar purpose [4]. The column was a ZB-35HT (Inferno) capillary GC column (30 m \times 0.25 mm with a film thickness of 0.25 μ m). The GC oven temperature program in the analyses of pyrolysis products was as follows: 2 min at 40 °C, 4 °C min⁻¹ to 190 °C, 10 °C min⁻¹ to 320 °C, and 10 min at 320 °C. Helium was used as the carrier gas with a gas flow rate of 1 mL min⁻¹ and as an inert atmosphere in the pyrolysis interface. Detection was carried out with an HP 5970 mass spectrometric detector under electron ionization (70 eV) with 2.92 scan per seconds in the 30–550 m/z interval.

Compounds were identified using the National Institute of Standards and Technology (NIST) mass spectral library. Quantitative analysis was conducted according to our previous study with a set of standard samples of known concentration based on duplicated injections [4]. To utilize this, standard solutions for the low concentration range of 0.05–1.0 mg mL⁻¹ and for the high concentration range of 1.0–8.0 mg mL⁻¹ were prepared, depending on the standard's chromatographic response (GC/MS). The conditions of the GC were set to those of the Py-GC/MS. To obtain the yields of GC-detectable products, a plot of instrument response (i.e., peak area, y -axis) versus amount of standard solution (μ g, x -axis) was performed. Therefore, the relative mass response of a target compound compared to the mass of the corresponding external standard was extracted from plot and the corresponding yield (supplementary S1-3) was calculated based on the initial sample. In addition, the quantification analyses are given in the supplementary data (S4).

Elemental analysis was performed with a CHNOS elemental analyzer GmbH (Vario EL III) to identify the content of carbon, hydrogen, nitrogen, and oxygen (Table 1). The tests were conducted in duplicates.

Results and discussion

Thermogravimetric considerations

The temperature at which decomposition reactions of wood occur and the changes in specimen mass associated with the reactions can be found by thermogravimetric analysis, which exactly recorded the mass loss of the solid sample versus temperature/time. Traditionally, the chemical kinetic models for the biomass and its components are proposed from the analysis of the different mass loss stages and validated through the correlation between the predicted data and the experimental mass loss curve. According to TG the mass loss of cellulose and hemicelluloses typically starts at about 100 °C (i.e., due to the loss of adsorbed water). At temperatures between 100 and 250 °C, the rate of mass loss is quite slow, but above 250 °C, it increases [19]. For example, cellulose undergoes an extensive endothermic–exothermic sequence immediately above 300 °C [20, 47], and it has been reported that for xylan, displaying clear exothermic behavior [48], the most intensive thermal degradation takes place in the temperature range 200–260 °C [19, 49].

Figure 1 shows TG and DTG curves of cellulose, glucomannan, and xylan. The average active pyrolysis ranges of 290–410 °C and 230–340 °C were observed for

Fig. 1 TG and DTG curves of cellulose, glucomannan, and xylan at 20 °C min⁻¹

cellulose and hemicelluloses, respectively. The higher thermal stability of cellulose (glucan-based polysaccharide), compared to amorphous hemicelluloses with several types of glycosidic bonds and side-groups, was mainly attributed to its unbranched and ordered (i.e., highly crystalline) structure [1, 19, 21, 41, 50]. Among the hemicelluloses, xylan had lower thermal stability than glucomannan. The pyrolysis char yield determined was 9, 27, and 25% of the initial mass for cellulose, glucomannan, and xylan, respectively. This finding agreed well with the earlier data [19, 51] and suggested more multiple reactions of heterogeneous hemicelluloses and their monosaccharide moieties. According to [51], the differences in the char yield between cellulose and hemicelluloses are clearly due to the somewhat different pyrolysis reaction mechanisms. The DTG peak heights (wt % s⁻¹) were as follows: cellulose 0.48 at 382 °C, glucomannan 0.25 at 316 °C, and xylan 0.57 at 304 °C.

The calculated, based on the Flynn–Wall–Ozawa method [52] activation energy (E_a), value as a function of fractional conversion (α) for cellulose, glucomannan, and xylan is presented in Fig. 2. It could be noted that the variation in E_a was slightly lower for cellulose (142–162 kJ mol⁻¹) than for glucomannan and xylan. In the literature, depending on the sample origin, a variety of E_a values for cellulose have been given; for example, an average value of 109.4 kJ mol⁻¹ [50]. The E_a value for glucomannan varied between 111 and 301 kJ mol⁻¹, and it gradually increased in the progress of pyrolysis. However, at the end of pyrolysis ($\alpha > 0.7$), a rapid rise (i.e., from 160 to 300 kJ mol⁻¹) was observed. This phenomenon has also been reported earlier by [53]. They also reported the E_a values between 181 and 206 kJ mol⁻¹ for glucomannan in the α range 0.1–0.75. In the case of xylan, the E_a value (168–200 kJ mol⁻¹) increased until $\alpha = 0.6$, and, after this point, it started to decrease. In the previous study [54], the E_a values for xylan were between 150 and 250 kJ mol⁻¹ in the temperature range 185–215 °C.

Fig. 2 Activation energy (E_a) as a function of fractional conversion (α) for cellulose, glucomannan, and xylan

It has been reported [55] that the significant variation in the E_a value with respect to α indicates a multi-step reaction mechanism. Practically, the present data suggested that cellulose degradation during pyrolysis proceeded via reasonably simple and straightforward mechanisms without any significant secondary reactions. In contrast, it could be concluded that, due to greater variation in the E_a values for hemicelluloses, their degradation during pyrolysis took place by somewhat more complicated reaction mechanisms as already indicated by the high-char yields. The thermal degradation of the polysaccharides studied occurred by versatile parallel reaction paths that were not characteristically specific for certain temperature ranges. Hence, with this respect, TG, without any definite detention possibilities, could not suggest distinct differences in their thermochemical degradation behavior.

Pyrolysis: gas chromatographic analyses

The integrated chromatographic system GC/MS applied resolved most of the low-molar-mass compounds released from the model substances during pyrolysis; altogether, 42 from cellulose, 47 from glucomannan, and 41 from xylan were identified in conformity with pure compounds and MS library. For simplicity, the dominant GC-amenable pyrolysis products were classified into illustrative compound groups by the same system as that used earlier for similar purposes [4, 5]. It could be roughly concluded that the groups of anhydrosugar (A), cyclopentenone (C), furan (F), indene (I), lactone (L), and pyrone (Y) derivatives originated from carbohydrates, and those of guaiacol (G) and phenol (P) derivatives originated from lignin. The characteristic groups of naphthalene (N) derivatives were obtained from extractives, whereas the groups of other aromatics, benzene (B) and linear ketones (LK) derivatives, were probably formed from all the model substances; examples of a typical pyrogram profile at 700 °C and 20 s, for each sample, are presented in Fig. 3, and the main compounds identified are listed in Table 2. Practically, pyrolysis experiments under the same conditions also led to reproducible results with reasonable accuracy. During the pyrolysis, a wide range of components have been detected and the mechanisms of the formation of several major products in this study are considered similar to those reported by Wang et al. [13]. It was assumed that principally, the formation of each compound group occurs via characteristic mechanisms and pathways. In the case of cellulose pyrolysis [15], ring-opening of glucopyranose units takes place to form open-chain structures, followed by dehydration and cyclization to generate 5-(hydroxymethyl)furfural (5-HMF), which further converts through the elimination of the hydroxymethyl group to produce furfural, and LG is produced by the cleavage of the β -(1 →

4)-glycosidic linkage in the cellulose macromolecules, followed by an intramolecular rearrangement. In the case of xylan pyrolysis Shen et al. [36] and Patwardhan et al. [51] have reported that the depolymerization and ring scission of xylan form ring-opened intermediates, which further produce linear ketone products, such as hydroxyacetone (via carbon chain fracture), furfural and lactones (by cyclization), and alicyclic ketones, such as cyclopentenones through the combination of C=C bonds. The degradation of glycosidic linkages between monomer units of glucomannan results in anhydrosugars and more

stable furan rings (such as 5-HMF, 5-MF, and furfural) [14, 53].

Most of these pyrolysis products have been detected earlier in related studies after pyrolysis of polysaccharides-containing samples or polysaccharides, although in different proportions [4–6, 14–17, 23, 29, 51, 56–60]. In our previous pyrolysis studies with birch wood [4] and spruce wood [5] as well as okra and miscanthus [6], there were several pyrolysis products, such as guaiacol, syringyl, naphthalene, and fatty acid derivatives, that originated from lignin and extractives. However, in this back up study, guaiacol and syringyl derivatives were detected only for xylan, indicating that the xylan preparation used contained some minor guaiacyl-syringyl-type lignin impurities. As a typical trend, in each case, the yield of GC-detectable pyrolysis products decreased steadily toward harsher pyrolysis conditions enhancing the formation of char and volatiles. Hence, the pyrolysis temperature should be shortened to maximize the yield of pyrolysis products (Figs. 4–6). All the compound groups with different relative formation rates were detected within the temperature range studied (500 °C, 600 °C, and 700 °C), except anhydrosugar derivatives (mainly LG and levoglucosanone), which were prominently obtained only from cellulose.

Figure 7 shows the formation examples of the selected main pyrolysis products from model substances and their formation decreased at the longer holding time (20 s) and the higher reaction temperature (700 °C). It could be noted that, for example, 3-hydroxy-2-penteno-1,5-lactone (lactone) was primarily formed from xylan (also partly from cellulose), 5H-furan-2-one (lactone) from glucomannan (also partly from cellulose), 3-methylcyclopentane-1,2-dione (cyclopentenone) from glucomannan, furfural (furan) from cellulose and xylan, and 5-HMF (furan) from cellulose. Based on the our previous studies [4–6], of these major pyrolysis products, especially 3-hydroxy-2-penteno-1,5-lactone was produced by a factor of three from hardwood [4] than from softwood [5] indicating the presence of a higher portion of xylan in hardwood. However, its yield from hardwood was still less than that from xylan, probably due to an effect of its integration with cellulose and lignin. In the case of 5H-furan-2-one, its formation was less in spruce than pure glucomannan due to their interaction. On the other hand, it decreased in delignified glucomannan-poor softwood samples even by a factor of six, and it could be claimed that this compound originated from glucomannan more readily than from cellulose. A decreasing trend of LG formation in untreated and treated softwood samples manifested that it was formed from both glucomannan and cellulose, but more from cellulose. Also 3-methylcyclopentane-1,2-dione and furfural, are

Fig. 7 Effects of temperature and time on yields of some prominent pyrolysis products

prominent products from birch wood and spruce wood as well as non-wood [6].

Formation of pyrolysis products

It was expected that the total amounts and the relative proportions of varying compounds and compound groups were characteristically dependent on pyrolysis conditions, although the total yield of pyrolysis products that are

normally recovered and identified from laboratory-scale pyrolyzers is generally known to be low [61, 62]. A great number of studies have been performed to clarify the reaction networks between the basic structural unit of cellulose, D-glucose, or β -(1 \rightarrow 4)-glycosidic bond-containing low-molar-mass model compounds (e.g., to clarify the role of the dehydration and retroaldol condensation reactions of anhydrosugars and the cleavage of glycosidic bonds) [11, 32, 46]. Typically, the products of cellulose pyrolysis in the classic lumped kinetic models are roughly divided into gases, tar, and char, rather than utilizing the detailed compound distribution. Earlier kinetic studies have been carried out under a variety of pyrolysis conditions, leading to somewhat conflicting data with a wide range of kinetic parameters [37]. Hence, it can be concluded that the kinetics and elementary-reaction chemistry of carbohydrate pyrolysis are still debated [29].

A comprehensive clarification of the myriad pyrolysis reaction routes for cellulose and hemicelluloses was beyond the scope of this study. Instead, the practical aim was to clarify the chemical composition of condensable liquids obtained from these feedstocks at varying temperatures for evaluating the chemical usefulness of the corresponding fractions. Table 3 illustrates the relative formation of the major product groups (lactone, furan, and cyclopentenone derivatives) from cellulose, glucomannan, and xylan under varying pyrolysis conditions, whereas the corresponding formation of the minor product groups (phenolic, pyrone, and anhydrosugar derivatives) is shown in Table 4.

Tables 3 and 4 indicate that no distinct compound group was selectively formed at certain temperatures and the major product groups lactone, furan, and cyclopentenone derivatives accounted for 72–85% (from cellulose), 86–90% (from glucomannan), and 76–81% (from xylan) of the total amount of pyrolysis products determined. In practice, this finding means that if a mixture of cellulose, glucomannan, and xylan with equal proportions would be pyrolyzed at 500 °C, about half of the condensable liquids will consist of lactone derivatives. In the case of cellulose, the proportion of lactone derivatives decreased, and that of anhydrosugar derivatives increased steadily as the temperature increased. For glucomannan and xylan, the proportion of lactone derivatives also decreased and the proportion of cyclopentenone derivatives was slightly depressed toward the maximum temperature. However, for all model substances, no significant changes in the proportion of furan derivatives could be detected. The corresponding major product groups were also prominent ones identified in our earlier pyrolysis experiments, especially at 500 °C, with wood and non-wood feedstocks [4–6] existing together with the lignin-derived significant product groups, guaiacol, and syringyl derivatives. Particularly in the wood

Table 3 Relative proportions (%) of major product groups obtained from cellulose, glucomannan, and xylan under varying pyrolysis conditions

Product group ^a	Cellulose	Glucomannan	Xylan
500 °C			
L	46 (1.8)	33 (1.1)	48 (2.0)
F	23 (0.8)	31 (1.0)	20 (0.8)
C	16 (0.5)	26 (0.8)	11 (0.4)
600 °C			
L	39 (1.1)	21 (1.5)	43 (1.5)
F	26 (0.7)	33 (1.1)	24 (0.8)
C	17 (0.5)	32 (1.1)	14 (0.5)
700 °C			
L	33 (0.6)	17 (0.4)	33 (0.7)
F	18 (0.4)	37 (0.9)	24 (0.7)
C	21 (0.4)	33 (0.6)	19 (0.6)

The values given in parentheses refer to yields (% of the initial feedstock dry matter)

Data from Figs. 4–6, calculated average values for heating times of 5 and 20 s

^aL refers to lactone derivatives, F to furan derivatives, and C to cyclopentenone derivatives

Table 4 Relative proportions (%) of minor product groups obtained from cellulose, glucomannan, and xylan under varying pyrolysis conditions

Product group ^a	Cellulose	Glucomannan	Xylan
500 °C			
P	1.3	3.1	9.0
Y	6.7	2.1	2.8
A	6.7	1.8	—
600 °C			
P	4.0	7.1	6.3
Y	5.6	2.4	4.2
A	8.5	1.5	—
700 °C			
P	9.3	10	10
Y	5.0	2.3	5.7
A	14	1.2	—

Data from Figs. 4–6, calculated average values for heating times of 5 and 20 s

^aP refers to phenolic derivatives, Y to pyrone derivatives, and A to anhydrosugar derivatives

pyrolysis cases, estimated in view of the present results, approximate calculations suggested that the proportions of these compound groups were almost equal to the expected ones.

Conclusions

Pyrolysis-based technologies can be described as direct thermochemical conversion methods of lignocellulosic biomass carried out in the complete or near complete absence of an oxidizing agent (air or oxygen) typically at 500–700 °C to provide complex fractions of gases, condensable liquids, and char. In many biorefinery concepts, pyrolysis has been applied to prepare fuels and platform chemicals. The pyrolytic degradation of biomass is dominated by the behavior of its structural components, carbohydrates (cellulose and hemicelluloses, such as glucomannan and xylan) and lignin.

In this study, the analytical pyrolysis of cellulose, glucomannan, and xylan was carried out at 500, 600, and 700 °C. In each case, the condensable liquids formed were analyzed in detail and classified into several characteristic compound groups. The results revealed that despite some general formation trends, due to many parallel reaction paths, no compound group was selectively formed at certain temperatures, and the major product groups lactone (the most prominent fraction), furan, and cyclopentenone derivatives accounted for 72–85% (from cellulose), 86–90% (from glucomannan), and 76–81% (from xylan) of the total amount of pyrolysis products determined. This study also confirmed by thermogravimetric analyses that within the temperature range studied, cellulose was thermally more stable than the heterogeneous hemicelluloses. All these findings supported those from versatile earlier research and facilitated the creation of a more coherent picture of this complicated area. These kinds of data are of practical importance with respect to efforts to develop new biorefinery possibilities for renewable resources.
