Rippling of two-dimensional materials by line defectsTopi Kähärä  and Pekka Koskinen ^{*}*Department of Physics, Nanoscience Center, University of Jyväskylä, 40014 Jyväskylä, Finland*

(Received 18 June 2020; accepted 5 August 2020; published 18 August 2020)

Two-dimensional materials and their mechanical properties are known to be profoundly affected by rippling deformations. However, although ripples are fairly well understood, less is known about their origin and controlled modification. Here, motivated by recent reports of laser-controlled creation of line defects in graphene, we investigate how line defects could be used to control rippling in graphene and other two-dimensional materials. By sequential multiscale coupling of density-functional tight-binding and continuum elasticity simulations, we quantify the amount of rippling when the number and the cumulative length of the line defects increase. Simulations show that elastic sheets with networks of line defects create rippling that induces considerable out-of-plane rigidification and in-plane softening with nonlinear elastic behavior. We hope that these insights help to guide experimental attempts to modify the mechanical properties of graphene and other two-dimensional materials.

DOI: [10.1103/PhysRevB.102.075433](https://doi.org/10.1103/PhysRevB.102.075433)**I. INTRODUCTION**

While graphene and other two-dimensional (2D) materials are often portrayed as planar sheets, real samples frequently contain ripples and other out-of-plane deformations [1,2]. Rippling deformations affect materials' mechanical, electronic, and thermal properties and are of pivotal importance for a number of applications.

From a mechanical applications point of view, the most notable effect of rippling is its propensity to increase the out-of-plane rigidity of 2D materials [3–6]. The magnitude of rigidity is important for kirigami applications [7], nanomechanical systems [8], mechanical resonators [9], cantilevers [10], material systems [11], and applications dependent on the thermal expansion coefficient [12], to mention six examples. Rigidity is equally important also for nanostructured membranes, nanoribbons in particular [13]. The application potential of customized rigidity is aptly illustrated by the mundane example of corrugated sheets as packaging materials; the customized rigidity of 2D materials can be envisioned to substantially expand the range of mechanical applications at the nanoscale [14].

In addition to mechanical properties, rippling affects also phononic and electronic transport. Directional rippling renders phononic transport anisotropic [15], while electronic transport is modified by pseudomagnetic fields induced by areas of local Gaussian curvature [16–19].

Finally, rippling changes the nature of interaction with substrates. Rigidified membranes conform poorly to the surface morphology and come into local, dispersed contact with the substrate, reducing adhesion [20]. Rippling can therefore be used to customize surface adhesion, adjust the extent of intercalation of foreign molecules, and modify various properties of multilayers [21,22].

Ripples can have several different origins. They can originate from thermal fluctuations, defects, adsorbates, and external stresses and their characteristics have been investigated by atomic force and transmission electron microscopies [4,23–34]. But whatever the origin, the list of applications above implies that achieving better control over rippling should be considered highly desirable.

It is therefore exciting that recent experiments have shown indications of controlled rigidification of graphene by using a technique called optical forging [35,36]. The technique, which consists of direct writing with a pulsed laser under inert atmosphere, creates defect structures of linear character [37,38]. The graphene samples in these experiments were initially supported, but in the resulting three-dimensional structures the forged graphene is essentially suspended, making the presence of substrates irrelevant. Modeling and experiments indicate that the forging process presumably creates line defects as arrays of adjacent Stone-Wales point defects [38]. Although the mechanical properties of rippled membranes as such are fairly well known [39], line defects as the source of rippling is not understood.

In this article, therefore, we pursue to investigate how line defects create rippling in 2D materials, by using a sequential multiscale approach. We start from atomistic modeling, using Stone-Wales line defects in graphene as prototypical, exemplary line defects. Results from these atomistic simulations are then fed into a mesoscale continuum model that enables investigating rippling at relevant length scales and makes the results generic to different 2D materials.

II. ELASTIC PARAMETERS FROM ATOMISTIC SIMULATIONS

To obtain parameters for the continuum model, we first investigate atomistic models for prototypical line defects. We consider line defects induced into pristine graphene, excluding grain boundaries and other topological defects that change

^{*}pekka.j.koskinen@jyu.fi

crystal orientation [40,41]. As discussed above, we focus on line defects inspired by observations from optically forged graphene samples that presumably contain linear arrays of Stone-Wales (SW) defects [38,42]. Although these line defects are neither fully characterized nor fully established, they enable the construction of concrete and feasible line defect models. In SW defects one carbon bond rotates 90° and forms two neighboring pentagons and two neighboring heptagons. The formation energy is large (4.6 eV) [42], but it reduces by as much as 1.5 eV when a second defect is formed near an existing one at suitable distance and orientation [38,43]. This attractive and anisotropic interaction makes pulsed laser irradiation auspicious for growing SW line defects [38]. Since the atomic arrangement of SW line defects is unknown, we content ourselves with creating four different model geometries and obtain rough magnitudes for the microscopic strain fields involved [Fig. 1(a)].

The model geometries are simulated by density-functional tight-binding (DFTB) theory [44–46], using the HOBIT code [47]. DFTB was chosen because it reproduces graphene's elastic properties well compared to density-functional theory (bending modulus 1.6 eV and Young's modulus 1.4 TPa) [48–50] and enables effective explorations across various system sizes by a few orders of magnitude faster calculations [51–60].

The line defects were modeled in a periodic, rectangular simulation cell of width w and length l_x [Fig. 1(a)], within which the SW defects were distributed along the x direction. Using a 10×1 k -point sampling, the geometries were optimized to force tolerance $0.005 \text{ eV}/\text{\AA}$ [61] and zero unit cell stress. The ultimate result from this procedure was the unit cell strain $\varepsilon(w) = \Delta l_x/l_x$ for different widths w .

As the central result, the unit cell strains were observed to scale as

$$\varepsilon(w) = \varepsilon_0 \frac{a}{w}, \quad (1)$$

where $a = 2.46 \text{ \AA}$ is the graphene lattice constant and ε_0 is a fit parameter characterizing the line defect in question [Fig. 1(b)]. Conceptually, the functional form implies that—from a continuum point of view—the presence of an atomistic line defect can be simply and accurately represented by a stripe of width a with a longitudinal strain ε_0 [inset of Fig. 1(b)]. The strain ε_0 for different line defect models varied in the range $\varepsilon \approx -10\%$ to 20% . While ε_0 has both negative and positive values, here we focus on positive values, meaning line defects with compressive stress. Only compressive stress can be released by rippling deformations when the defect density is low. Such rippling is demonstrated at atomic scale by the planar model LD₃, in which the compressive stress is reduced by a slight out-of-plane buckling [Fig. 1(b)]. Conversely, tensile stress can be released by rippling only at defect densities high enough to fall beyond the scope of this work. One example of a line defect with tensile stress is LD₄, in which rotated bonds and the compressive stress orient perpendicular to the line defect [62,63].

To summarize the atomistic simulations, the central results are the scaling in Eq. (1) and the range of strains $\varepsilon_0 \approx 10\text{--}20\%$. There would have been many more possibilities for atomic structures of line defects, but obtaining a rough

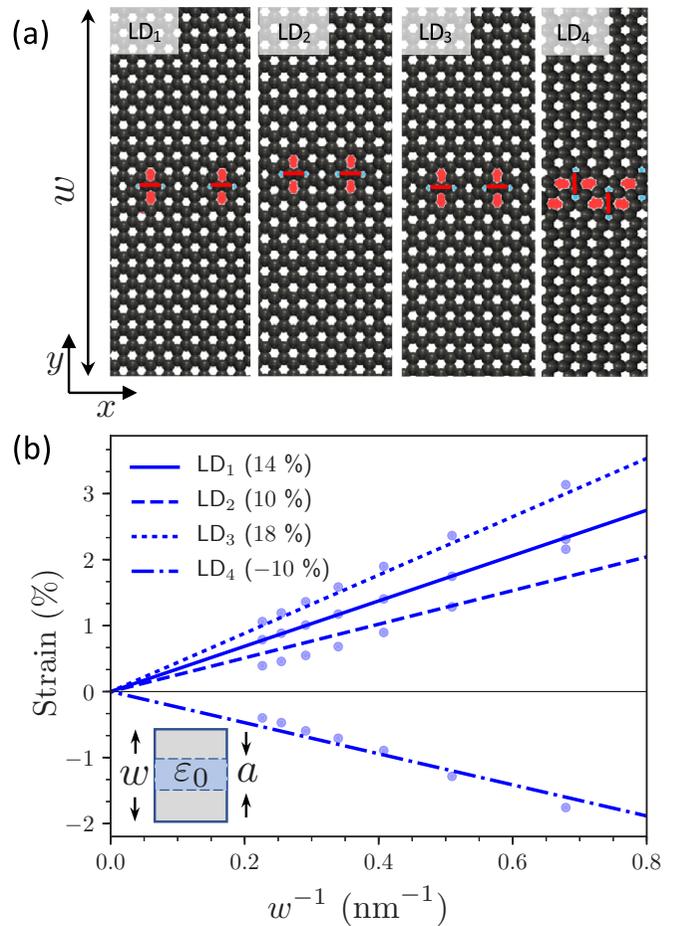

FIG. 1. Mesoscopic elasticity of line defects from atomistic modeling. (a) Four Stone-Wales line defect (LD) models, enclosed in simulation cells of width w from 1.6 to 4.7 nm. Cell length l_x was optimized for each w to get the strain $\varepsilon(w) = \Delta l_x/l_x$ along the line defect. The rotated bonds (red bars), surrounded by pentagons (blue shading) and heptagons (red shading), indicate the direction of compressive stress. Line defect models are all planar except for LD₂, where the peak-to-peak out-of-plane corrugation is 0.9 \AA . (b) Unit cell strains $\varepsilon(w)$ for each line defect model. Strains are fitted to the functional form $\varepsilon(w) = \varepsilon_0(a/w)$, where ε_0 (in brackets) is a line-defect-dependent fit parameter and $a = 2.46 \text{ \AA}$ is the graphene lattice constant. Inset: The effect of the line defect on the mesoscale is equivalent to a strip of width a strained longitudinally by ε_0 .

range of strains suffices for our purposes. Knowledge of the range allows us to proceed to mesoscale continuum elasticity modeling, which can use Eq. (1) to account for the presence of line defects consistently with respect to the discretization length.

III. CONTINUUM ELASTICITY SIMULATIONS

A. The elasticity model

The continuum elasticity model we use is similar to the one introduced in Ref. [64] and used in Ref. [55] in the context of carbon nanotubes. The sheet is modeled as a hexagonal lattice of linear springs of equilibrium length d and spring constant \tilde{k}_s . The in-plane strain energy of a spring connecting vertices

A and B is thus

$$E_s = \frac{1}{2} \tilde{k}_s (|\vec{r}_{AB}| - d)^2, \quad (2)$$

where $|\vec{r}_{AB}|$ is the distance from A to B . The bending energy related to neighboring vertices A and B is given by

$$E_b = \frac{1}{2} \tilde{k}_b \theta_A^2 + \frac{1}{2} \tilde{k}_b \theta_B^2, \quad (3)$$

where \tilde{k}_b is a parameter controlling the bending rigidity and θ_X is the angle between the vector \vec{r}_{AB} and the unit normal vector \hat{n}_X at vertex $X \in \{A, B\}$. The normal vector \hat{n}_X is defined as the area-weighted mean of the normal vectors of the triangles surrounding the vertex.

In the continuum limit of the model, the energy density for small uniaxial strains ε is approximately

$$F_s = \frac{3\sqrt{3}}{8} \tilde{k}_s \varepsilon^2 \equiv \frac{1}{2} k_s \varepsilon^2. \quad (4)$$

Similarly, the energy density for pure bending at bending radius R is

$$F_b = \frac{3\sqrt{3}}{16} \frac{\tilde{k}_b}{R^2} \equiv \frac{1}{2} \frac{k_b}{R^2}. \quad (5)$$

The quantities k_s and k_b in Eqs. (4) and (5) are the uniaxial strain modulus and the bending modulus of the sheet, to be compared with literature values.

This model was implemented in PYTHON using a rhombic cell with periodic boundary conditions. The cell length was $l_{\text{cell}} = 120$ nm and discretization length 2 nm (unstretched spring lengths). These values are sufficient for a faithful continuum description of the type of rippling we focus on. The strain modulus was $k_s = 26$ eV/Å², which is comparable to the strain modulus of graphene, while it represents roughly also other 2D materials such as hexagonal boron nitride and transition-metal dichalcogenides [4]. In order to obtain different ratios for k_s/k_b and thereby represent materials with various rigidities [4,50,65,66], values of the bending modulus k_b were chosen as 13, 26, and 52 eV. The bending moduli are greater than inferred from atomistic *ab initio* calculations for flat graphene, but still significantly smaller than values measured for graphene samples, and are expected to be realistic considering the discretization length [4,6]. Reiterating, although our atomistic simulations involved only graphene and certain line defect models, we use generic parameters with the intention to get a broad view of the effect of line defects on the rippling on 2D materials; our elasticity model is fully general.

In the model, the strain fields from line defects were represented by the stretching of bonds. The magnitude of stretching was determined by adopting a sequential multiscale strategy, which implied that parallel strains induced by atomic scale defects are inversely proportional to the width of the system, as given by Eq. (1). Then, for a given distribution of line defects and the concomitant strain field, the minimum energy geometry was determined by the Limited-memory Broyden–Fletcher–Goldfarb–Shanno (L-BFGS-B) optimization method with a relative accuracy of 10^{-7} , meaning a total energy tolerance below 0.1 eV. Also the cell size was optimized for each strain field. Using the Nelder-Mead simplex method implemented in the SCIPY optimization library [67], cell size was optimized to 0.1 Å accuracy.

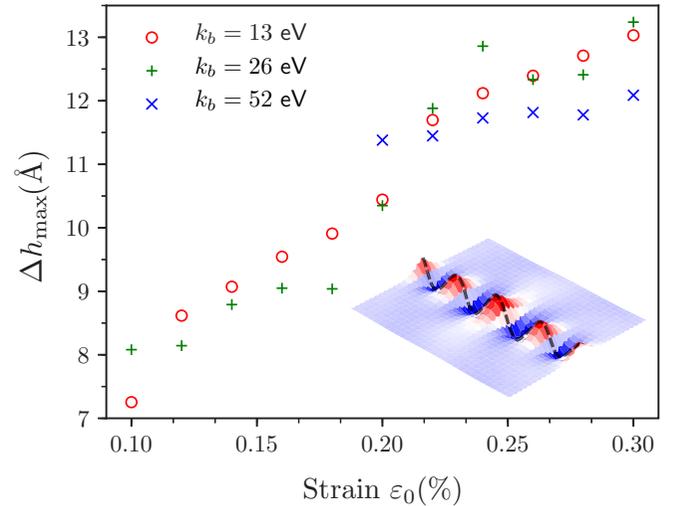

FIG. 2. Rippling with an isolated line defect. Plot shows the maximum height variation of the sheet, Δh_{max} , as a function of ε_0 for three different values of k_b . Inset: Optimized geometry of an isolated line defect (dashed line) with $\varepsilon_0 = 10\%$ and $k_b = 26$ eV.

The effective elastic moduli of the rippled sheets—the actual measurable quantities in typical experiments—were calculated by modifying cell sizes and boundary conditions. The effective strain moduli k_s^{eff} were calculated by straining the cells uniaxially to 4% maximum strain. The effective bending moduli k_b^{eff} were calculated by adapting the boundary conditions to cylindrical symmetry, in the spirit of revised periodic boundary conditions [53,58]. The smallest radii for determining the bending modulus were ten times the cell length. For these small strains and small curvatures the effective moduli could then be extracted directly from the energy density profiles through Eqs. (4) and (5).

To get progressively deepening insight into the effect of line defects on rippling, we investigated three different line defect scenarios: (i) an isolated line defect, (ii) a hexagonal line defect lattice, and (iii) a random network of line defects. We investigated these scenarios using different values of compressive strain ε_0 and increasing cumulative lengths of the line defects.

B. Limit of low defect density: Isolated line defects

In the first scenario we had a single, isolated defect spanning across the sheet. We chose the width w in Eq. (1) equal to the lattice constant of 2 nm, representing a transformation of given ε_0 into appropriate mesoscopic strain. An illustrative sample of the resulting optimized structure reveals rippling surrounding the line defect (Fig. 2). This type of rippling is familiar from the everyday behavior of clothes and fabrics. It also agrees with the reported rippling at the edges of semi-infinite graphene membranes [68,69]. The ripple amplitude increases as a function of ε_0 . The increase is steady, although slightly nonmonotonous due to finite size effects; the cell can accommodate only a discrete number of waves along the line defect. Note that, at least within the given strain range, the bending modulus has only a small effect on the ripple

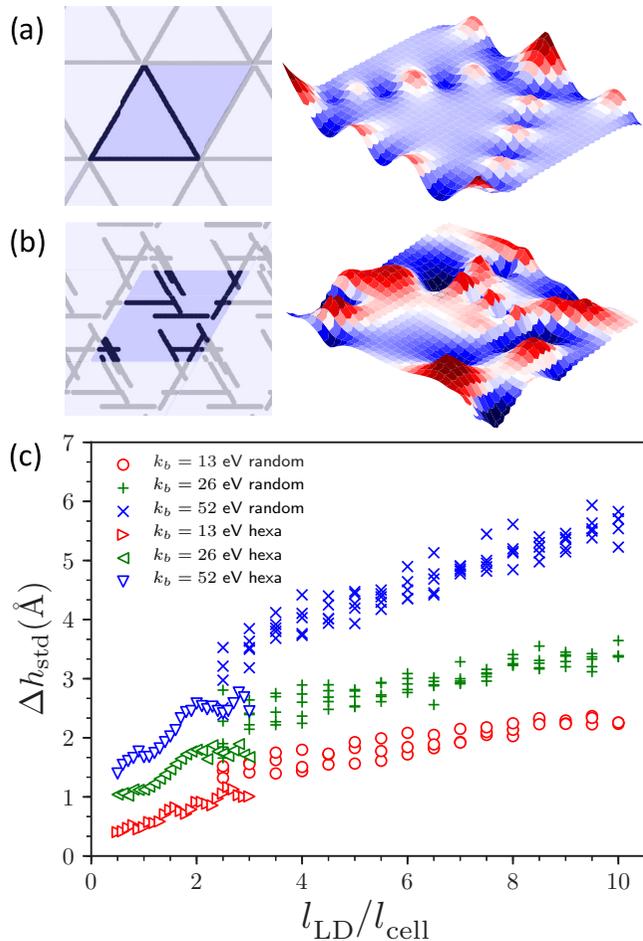

FIG. 3. Rippling with hexagonal and random line defect networks. (a) The geometry of a hexagonal line defect network with cumulative length of line defects $l_{\text{LD}} = 3l_{\text{cell}}$ (left), together with the resulting rippling for $k_b = 26$ eV (right). The copies of the simulation cell on the left are shaded. (b) The geometry of a random line defect network with $l_{\text{LD}} = 5l_{\text{cell}}$ (left), together with the resulting ripples for $k_b = 26$ eV (right). (c) Standard deviation of sheet height as a function of the cumulative length of line defects for different scenarios of networks and values of k_b .

amplitude. This trivial behavior indicates that the geometry is dominated by strain energy.

C. Interacting defects: Hexagonal and random line defect networks

Hexagonal and random line defect network scenarios yield similar results and we therefore discuss them simultaneously. Here the main variable is l_{LD} , the cumulative length of all the line defects, and especially its ratio to the cell length l_{cell} . In the hexagonal scenario, defects were grown from single points toward six symmetric directions, increasing the defect length until the lines became fully connected, with maximum cumulative length of $l_{\text{LD}} = 3l_{\text{cell}}$ [Fig. 3(a)]. In the random line defect scenario the cumulative line defect length could be larger and was varied from $2.5l_{\text{cell}}$ to $10l_{\text{cell}}$. Random line defect networks were investigated with 10, 20, and 30 separate line defects with both uniform and linear length

distributions, in order to mimic the type of networks proposed in Ref. [38] [Fig. 3(b)]. It turned out that neither the number of line defects nor the type of their length distribution made noticeable difference in the trends; below we show results for all defect numbers and distributions.

As in the previous section, both hexagonal and random scenarios are simulated for three values of bending moduli. We used $\varepsilon_0 = 10\%$ with $k_b = 13$ and 26 eV and $\varepsilon_0 = 20\%$ with $k_b = 52$ eV. Larger ε_0 for the largest k_b was necessary because a stiff sheet made it difficult to discern reliable trends in those situations when a small ε_0 was supplemented by small l_{LD} .

As a clear trend for both scenarios, the rippling intensifies steadily upon increasing cumulative length of line defects. The intensifying is evident in the increase of the standard deviation in the height distribution [Fig. 3(c)]. Standard deviation is a robust quantity easy to obtain from the model and determinable also from experiments, unlike peak-to-peak amplitudes that are subject to wild fluctuations. Especially the hexagonal scenario shows peaked corners, while other areas remain only modestly rippled [Fig. 3(a)]. For both scenarios the standard height deviation increases roughly linearly with increasing l_{LD} , although for the hexagonal scenario it is noticeably smaller, visible around $l_{\text{LD}}/l_{\text{cell}} \approx 3$ where the data from the two scenarios overlap. This difference arises presumably because in the hexagonal scenario the line defects with given l_{LD} have maximal spatial separation and are consequently less prone to spread ripples effectively throughout the sheet.

When l_{LD} increases, also the total surface area of the sheet expands. This area is sometimes referred to as the hidden area, as it does not necessarily result in actual lateral expansion [10]. Indeed, as a consequence of the very low bending stiffness compared to strain modulus, the sheet prefers rippling over lateral expansion. A similar phenomenology is responsible for the negative thermal expansion coefficient of graphene [70]. However, with the given material parameters the changes in lateral cell dimensions were small enough to render the nature of lateral behavior inconclusive.

Finally, we proceed to the main results, which discuss how line defect networks—through rippling—affect 2D materials' effective elastic properties.

Among the most notable results is the highly nonlinear elastic behavior of strained sheets. This nonlinearity can be seen as a strongly strain-dependent effective strain modulus k_s^{eff} [Fig. 4(a)] [10]. The modulus at strains around 0.5% is tens of percent smaller than at strains around 4%. This trend can be understood in geometric terms: small strains involve the flattening of the initial ripples and concerns mostly (cheap) bending energy, while large strains involve the further stretching of the already flattened sheet and concern mostly (expensive) stretching energy. Thus, at the limit of large strain, the effective strain modulus necessarily approaches k_s . This geometrical picture is consistent with the decrease of k_s^{eff}/k_s upon increasing l_{LD} [compare Figs. 3(c) and 4(a)].

In contrast to the nonlinear behavior of the effective strain modulus, the effective bending modulus turned out to be a well-defined quantity, independent of the applied bending radius. The effective bending modulus shows a clear increasing trend upon increasing l_{LD} [Fig. 4(b)]. This trend

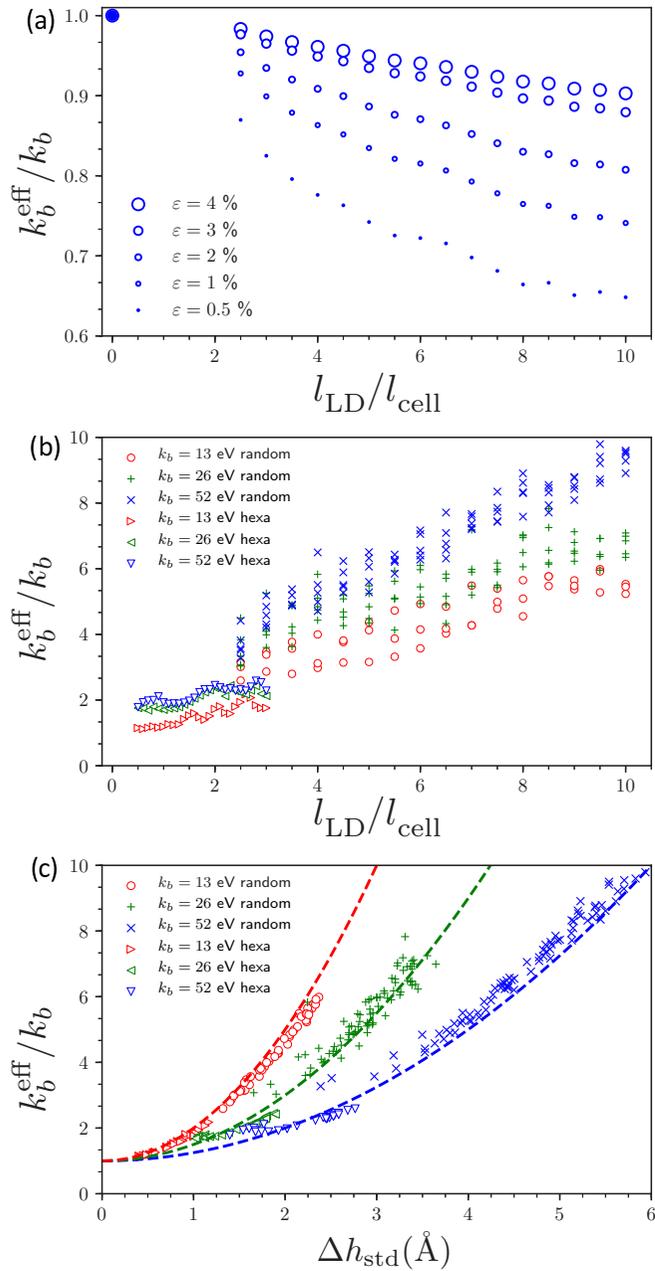

FIG. 4. Effective elastic moduli of elastic sheets with line defect networks. (a) Relative changes in effective strain moduli (k_s^{eff}/k_s) of rippled sheets as a function of the cumulative line defect length l_{LD} for random line defect networks, demonstrating nonlinear elasticity. The effect of k_b on k_s^{eff} was small, whereby the values were averaged over different k_b . (b) Relative changes in effective bending moduli (k_b^{eff}/k_b) of rippled sheets as a function of the cumulative line defect length, for different k_b and scenarios of line defect networks. (c) The relative change in the effective bending modulus (k_b^{eff}/k_b) as a function of rippling intensity measured by the standard height deviation. The dashed curves are given by Eq. (6).

is much expected, in view of the well-known stiffening effect of ripples in thin membranes [39]. Interestingly, the slope between k_b^{eff}/k_b and $l_{\text{LD}}/l_{\text{cell}}$ is roughly 1, although for larger k_b the stiffening is more pronounced. Moreover, around $l_{\text{LD}}/l_{\text{cell}} \approx 3$, the effective bending modulus is larger

with random line defects than with hexagonal line defects, in line with a corroborating trend in standard height deviation [Fig. 3(c)].

The origin for the trend in the effective bending modulus is illustrated particularly well when k_b^{eff} is plotted as a function of the standard deviation Δh_{std} of the sheet height [Fig. 4(c)]. The relation between k_b^{eff}/k_b and Δh_{std} fits well with the quadratic expression

$$\frac{k_b^{\text{eff}}}{k_b} = 1 + \frac{1}{2} \frac{k_s}{k_b} \Delta h_{\text{std}}^2. \quad (6)$$

The expression can be justified by a simple dimensional analysis and the limit $k_b^{\text{eff}} \rightarrow k_b$ as $\Delta h_{\text{std}} \rightarrow 0$; the factor $\frac{1}{2}$ is a (convenient) fit parameter. This expression is consistent with the small ripple amplitude result from Ref. [39], but inconsistent with the asymptotic scaling for large ripples predicted in the same paper. We therefore expect relation (6) to become invalid at larger scales. Nevertheless, the spatial character of rippling caused by line defects, even if randomly displaced, may differ from the spatial character underlying random rippling assumed in Ref. [39]. Relation (6), the spatial character of rippling, and the nature of rigidification thus deserve further investigation.

IV. SUMMARY AND CONCLUSIONS

In this work we used sequential multiscale modeling to investigate the influence of line defects on the mesoscopic elastic properties of two-dimensional materials. Inspired by recent experiments, we used arrays of Stone-Wales defects as the prototypical models of nontopological, atomic-scale line defects [38]. Density-functional tight-binding calculations were used to obtain reasonable parameters for mesoscale continuum modeling by using the scaling law of Eq. (1). The mesoscale modeling was then framed at a couple of orders of magnitude larger length scales and with parameters that reflected our attempt to obtain generic results for the elastic properties representing various 2D materials.

The modeling showed that sheets ripple predictably as the number, the intrinsic strain ϵ_0 , and the cumulative length of line defects, l_{LD} , increase (Figs. 2 and 3). The increased rippling consequently reduces the effective elastic modulus and substantially increases the effective bending modulus of the sheet (Fig. 4), in line with findings in earlier reports. These results are well in line with the experimentally observed disparity between atomic and mesoscale elastic properties of 2D materials [7]. We also provided a useful relationship [Eq. (6)] between the rigidification of the sheet and the magnitude of its ripples due to the presence of line defects.

In conclusion, the multiscale model has turned out useful in bridging the gap between the atomic and mesoscale elastic properties of 2D materials. While the atomic models were specific to graphene, the results were made generic for various atomically thin materials with comparable parameters. Should experiments discover mechanisms to create line defects in materials other than graphene, the multiscale formalism could readily be used to explore their quantitative influence on mesoscale mechanical properties. However, we hope that already the results above will give insight into the influence

of rippling by line defects and thereby further guide experimental attempts to modify the mechanical properties of 2D materials.
