ABSTRACT

Restoration of damaged ecosystems has become an important tool to slow down the biodiversity loss and to maintain ecosystem services. Peatland bird populations have shown a substantial decline during the recent decades in Northern Europe as a consequence of peatland drainage. We studied whether restoration of peatlands drained for forestry affects bird communities. We conducted bird surveys at 11 peatlands in Western Finland, where each of the restored and their pristine counterparts were surveyed before restoration and yearly after restoration during 2010–2018. We used linear mixed effect models to analyze whether restoration affected the number of species and territories of peatland specialist and non-specialist species and permutational multivariate analysis of variance to analyze the change in community composition. Drained parts of the peatlands had higher number of territories of non-specialist species before restoration, and restoration seemed to decrease these numbers towards the level of pristine parts. By contrast, restoration did not affect the number of peatland specialists and their territories, which was lower in drained than in pristine parts of the peatlands. Bird communities in restored parts remained different from pristine parts in terms of community composition after restoration. Thus, despite the effect of restoration on non-specialists, a substantially long time may be required for a recovery of the peatland bird communities. Based on our results, it seems that long term monitoring of the restored and pristine peatlands is needed to determine whether restoration is effective in recovering the peatland specialist bird species and bird communities in general.

Key words: biodiversity, community ecology, conservation, disturbance, draining, mire birds

Implications

- Ecological restoration of peatlands decreased the abundance of non-specialist bird species and tended to halt the decline of peatland specialist species, which is a general trend in pristine peatlands. However, these effects were not very strong.
- The general bird community composition still differed between pristine and restored peatlands at the end of the study period, implying that the full recovery of the peatland bird community is uncertain and will take a substantially long time.
- Pristine peatlands are essential habitats for peatland specialist bird populations and a source of colonization for restored peatlands.
- To halt the decline of the peatland specialist species, maintaining pristine areas undisturbed and initiating ecological restoration of the degraded peatlands as soon as possible is needed.

INTRODUCTION

Globally, less than a quarter of the land area remains free from significant anthropogenic impact (IPBES 2018). Climate change and land-use change, coupled with other anthropogenic disturbances, have led to declines in population sizes as well as species extinctions, with consequent effects on ecosystem functioning (Butchart et al. 2010; Barnosky et al. 2011; Cardinale et al. 2012). Ecological restoration, defined as an intentional activity that initiates or accelerates the recovery of an ecosystem (SER 2004; Gann et al. 2019), has a potential to slow down the biodiversity loss and maintain ecosystem services (Hobbs & Harris 2001; Hobbs & Cramer 2008; Bullock et al. 2011). Under the Convention on Biological Diversity (CBD), the governments of the global society have agreed to restore 15% of the degraded ecosystems by 2020 (UNEP, CBD & COP 2010). It is clear that this target is not going to be met, and therefore, United Nations General Assembly (UNGA) declared the decade 2021-2030 as the decade of ecosystem restoration (UNGA 2019). The aim of this resolution is to scale up the ecological restoration of degraded and destroyed ecosystems as a proven measure to fight the climate crisis and enhance biodiversity.

One of the most degraded habitat types are wetlands and peatlands of which over 70% have been destroyed during the last 300 years (IPBES 2018). Peatlands alone cover 4 million km² (3%) of the world's land area (Parish et al. 2008; Erwin 2009). In their natural state, they play an important role in global carbon cycle (Yu et al. 2011; Andersen et al. 2017) and have a unique species composition, thus being of high value to biodiversity (Littlewood et al. 2010; Minayeva et al. 2017). The greatest factors responsible for peatland degradation have been drainage for forestry and transformation to agricultural lands (Joosten & Clarke 2002).

The natural pristine state of the peatlands, together with hydrology and carbon storing capacity, recover faster through restoration (Jauhiainen et al. 2002; Vasander et al. 2003; Haapalehto et al. 2014). However, recovery may be incomplete and in many aspects the restored peatlands may differ greatly from their pristine state (Moreno-Mateos et al. 2012; Haapalehto et al. 2017). Indeed, a full recovery of peatland biota may take several decades (Gorham & Rochefort 2003; Moreno-Mateos et al. 2012), even though a significant number of typical peatland species can recover in 3–5 years (Gorham & Rochefort 2003; Noreika et al. 2015). Ecosystem functioning such as carbon sequestration may recover faster than the characteristic species composition (Kareksela et al. 2015). Several peatland bird populations have declined during recent decades in Europe (Hancock et al. 2009; Fraixedas et al. 2017; Lehikoinen et al. 2019). In Finland, the decline of peatland bird populations has been particularly severe (Fraixedas et al. 2017), and currently 58% of bird species using primarily peatlands for breeding are on the Red List (Lehikoinen et al. 2019). This is likely to reflect the fact that in Finland 60% of peatlands have been drained for agriculture and forestry (Aapala et al. 2013; Kaakinen et al. 2018). The major effect of drainage is a water level drawdown by 20–60 cm (Laine & Vanha-Majamaa 1992; Haapalehto et al. 2011). This causes significant changes in hydrology, acidity, and nutrient gradients (Holden 2005) which in turn change peatland vegetation (Elo et al. 2016). Restoration aims to reverse these changes by filling in and blocking the ditches as well as cutting the trees grown after drainage (Penttinen 2015). In Finland, the area of restored peatlands was approximately 32 400 hectares by the end of the year 2017 (Kaakinen et al. 2019).

There is a paucity of studies on the effect of peatland restoration on birds as most of the studies concentrating on the effect of peatland restoration have focused on vascular plants and bryophytes (Tahvanainen et al. 2002; Rochefort et al. 2003; Lucchese et al. 2010; Haapalehto et al. 2011; Wortley et al. 2013; Andersen et al. 2017). In addition, the ecological requirements of peatland bird species are

understudied (Newey et al. 2016; Fraixedas et al. 2017), hindering our ability to predict their response to restoration. However, peatland specialist species seem to prefer openness and wetness (Järvinen & Sammalisto 1976; Väisänen et al. 1998; Fraixedas et al. 2017), and have lower preferences for ditched peatlands (Väisänen & Rauhala 1983; Fraixedas et al. 2017). Thus, we expect that peatland specialist species are likely to benefit from ecological restoration. Indeed, some peatland bird monitoring programs have shown a positive effect of restoration after less than 10 years (Brown & Batzer 2001). For example, in United Kingdom Golden Plover (*Pluvialis apricaria*) was shown to benefit from peatland restoration in three years. The success was attributed to the increased abundance of crane flies, an important food source for the species, caused by the recovered higher water levels (Pearce-Higgins 2010; Carroll et al. 2011; Pearce-Higgins 2011).

A substantial part of the European peatland birds migrates to Finland to breed (Tiainen et al. 2010), and relative to the area, Finland has the highest share of peatlands in the world (Lappalainen 1996; Vasander et al. 2003). Therefore, Finland has a high responsibility in international peatland bird conservation (Tiainen et al. 2010, Lehtikoinen et al. 2019). The aim of this study is to determine whether ecological restoration as commonly implemented on forestry drained peatlands in Finland has an overall effect on recovery of the bird communities. In a longitudinal monitoring study, we analyze the bird communities, numbers of bird territories and number of species before and after restoration in comparison to pristine counterparts. We hypothesized that by increasing the openness and wetness of the peatlands, restoration increases the number of peatland specialist species and their territories, decreases the number of non-specialist species and their territories, and thus results in changes in bird community composition.

METHODS

Study set-up

The study was conducted on 11 peatlands located in Western Finland (Table 1, Fig. 1), and it was part of the Boreal Peatland LIFE project 2010–2014. The aim of the restoration was mainly to improve the ecological quality and recreational value of Natura 2000 priority peatland habitats such as Aapa mires, Bog woodlands and Active raised bogs (Penttinen 2015). The 11 peatlands selected for the study were originally either pine dominated or treeless mires (referred commonly as peatlands), which were partially ditched to initiate draining and facilitate tree growth during the 1960s and 1970s. Each of the peatlands included a treatment part that was initially drained and subsequently restored during the LIFE project, and a pristine counterpart that was used as a control (see Fig. 2). The area of the treatment part varied between 4.7 and 23.3 ha, and a control part of identical shape and size was established in the pristine counterpart. Control parts were always close to their treatment parts to reduce the differences in abiotic and biotic factors affecting the site. This design was also taken into account when analyzing the data (see *Statistical analyses*). The distance between the treatment and control parts ranged from 0.39 to 2.36 km, being on average 1.06 km.

We sampled the birds before restoration in the year 2010. One treatment part was restored already in 2005 and was thus not sampled before restoration (Table 1). The rest of the treatment parts were restored during the years 2010–2012. Since the peatlands included in the study were ditched for forestry resulting in decreased water levels and sometimes enhanced tree growth (Laine & Vanha-Majamaa 1992; Haapalehto et al. 2011), the restoration actions aimed to reverse these effects. Thus, restoration was conducted by filling in the existing ditches with peat, and constructing dams to raise water levels. In cases where drainage had increased tree growth open habitats were created by cutting the trees with a chain saw and removing them.

Tree removal is a significant restoration act aside of rising water levels influencing systematically the vegetation structure of the restored peatlands and peat formation. After restoration, we repeated the censuses yearly in each of the treatment and control parts during the years 2011–2018. The total number of sampling years differed from one to five depending on the year when the restoration was conducted on the treatment part (Table 1). Control parts always had the same number of censuses than the treatment counterparts.

We used the territory mapping of birds as a census method (Kendeigh 1944) in both pristine and restored parts, and yearly censuses were performed during the recommended census period between 30th May and 20th June. We performed the censuses between four and ten a.m. in dry and calm weather by walking slowly (1.5 km/h) along the predefined 50-meter wide transect, which covered most of the census area, using a map and GPS. All the observed territories of birds in transects were marked on the map. We considered 1) a seen or heard male, 2) a pair, 3) a lonely female, 4) a brood or 5) a nest as a territory. We classified all the observed bird species in two classes. Peatland specialist species were classified after Rajasärkkä (2013) accompanied by two species, *E. rustica* and *E. schoeniclus*, after Fraixedas et al. (2017). The rest of the species were considered as species not specialized on peatlands (non-specialist species). Some of the species classified here as peatland specialists also inhabit other open habitats (e.g., waterfront meadow and arable land). However, the Finnish populations nest primarily on open or pine dominated peatland habitats (FinBIF 2020). Therefore, we followed the Finnish classification by Rajasärkkä (2013) and Fraixedas et al. (2017).

Statistical analyses

Accepted Article

First, we analyzed whether restoration had an effect on 1) species richness of all birds, 2) species richness of peatland specialist species, 3) species richness of non-specialist species, 4) number of territories of all birds, 5) number of territories of peatland specialist birds, and 6) number of territories of non-specialist species. We used linear mixed models and entered sampling area, treatment ('Treat', where "0" refers to pristine and "1" to restored parts), sampling year, years since restoration and the interactions between treatment and sampling year, and treatment and year since restoration as fixed factors. We added the study site as a random factor to control for the site-specific differences in bird community compositions, as the control and treatment parts were located near to each other. We developed a complete set of models including all explanatory variable combinations for the six different response variables, separately. Because years since restoration and sampling year were highly correlated ($r = 0.85$), we restricted the model set not to contain these variables in the same model. To enhance the normality and homoscedasticity of the model residuals we \log_{10} -transformed the response variables and sampling area. In addition, we centered to zero and scaled sampling year and year since restoration. We used Akaike Information Criterion for small sample sizes (AICc) to compare the models within a set. The model with the smallest AICc is considered the best with respect to expected Kullback-Leibler information lost (Burnham & Anderson 2002).

As the best model in the set was not always apparent, we calculated the relative importance (I) of each variable using the models for which $d_i < 5$, where $d_i = \text{AICc}_i - \text{AICc}_{\min}$ is the Akaike distance d of each model i (Burnham & Anderson 2002). I is a sum of Akaike weights over all of the models in which the variable appears, and it ranges from zero (not important) to one (highly important). We also calculated model-averaged parameter estimates and their standard errors from the models with $d_i < 5$. Further, we ensured that there was no spatial autocorrelation in the residuals of the best models with Moran's I statistic.

Second, we analyzed whether restoration had an effect on the bird community composition. For this analysis, we used only the sampling years 2010 (before the restoration) and 2018. The site where the treatment part was restored already in 2005 was excluded from the analysis resulting in $n=10$. We calculated two dissimilarity indices: occupancy-based Sørensen's index and abundance-based Bray-Curtis index (Magurran 2004). We used permutational multivariate analysis of variance (PERMANOVA) which is a nonparametric test relying on permutations and can be based on any dissimilarity measure (Anderson 2001). The test is sensitive to differences in the dispersion of sites, even though the locations (i.e., mean community composition) do not differ (Anderson 2001). Thus, to infer whether community dispersions vary among the four groups (pristine 2010, before restoration 2010, pristine 2018, after restoration 2018) we used the distance-based test for homogeneity of multivariate dispersions (Anderson 2006). It is essentially a multivariate extension of Levene's test of homogeneity of variances and can be based on any distance or dissimilarity measure. The procedure counts the distance of each part to the multivariate centroid of the group, and statistical significance is tested by permutation of residuals (999 permutations) (Anderson 2006). PERMANOVA analyses were done in R (version 3.5.1, R Development Team 2017) with 'adonis2' function and multivariate dispersion with 'betadisper' function in the "vegan" package (Oksanen et al. 2013). We also used packages "nlme" (Pinheiro et al. 2019) to analyze linear mixed models for the number of species and number of territories for all birds, peatland specialist species, and non-specialists, and "MuMIn" (Barton 2019) for model selection.

The average temperature during the last sampling spring (13.7°C) in Central Finland (May 2018) was 4–5°C warmer than the long-term average (Ilmatieteenlaitos 2019a) which may affect the activity of the birds (Slagsvold 1977). However, since our sampling scheme was paired, and restored and pristine parts were sampled within a short time period (six hours), it is likely that the activity of the birds is similar in both parts and this should not bias our results.

RESULTS

During the study period, we observed 62 bird species and 1166 territories (Table S1). Sixteen species were classified as peatland specialists and they had altogether 382 territories (Table S1).

Number of all species and their territories

The total number of bird species and the number of their territories was higher in restored than in pristine parts before restoration and throughout the study period (Table S2, Fig. 3a,d). The models gave only little support for the effect of restoration on the number of species or territories of all bird species (Tables S2 & S3). By contrast, the larger the area, the higher the number of both species and territories (Tables S2 & S3).

The number of territories became smaller throughout the years, irrespective of whether the part was restored or pristine (Table S2, Fig. 3d).

Number of peatland specialist species and their territories

The number of peatland specialist species and their territories was higher in pristine than in restored parts before restoration, but the difference seems to become smaller during the years (Table S2, Fig. 3b,e).

However, there was only little support for the effect of restoration on the number of peatland specialist species or the number of their territories (Tables S2 & S3). The best models for the number of peatland specialist species and their territories explained 5% and 6% of the variation, respectively, which is substantially smaller than the variance explained by the best model for the non-specialist species (54% for

the number of species and 56% for the number of territories). It is also notable that there was support for various models, and none of the models was clearly better. Thus, the number of peatland specialist species and their territories was not very well explained by the explanatory variables used here.

Number of non-specialist species and their territories

The number of species and territories of non-specialist specialist species was higher in restored than in pristine parts before restoration and throughout the study period (Table S2, Fig. 3c,f). There was support for an effect of restoration on the number of both species and territories of non-specialist species as the interaction between sampling year and treatment was included in the best model (Table S3). During the years, restoration had a negative effect on the number of species and territories i.e., their numbers decreased while in pristine parts they seemed to remain as they were (Table S2, Fig. 3c,f). However, the observed decline is not particularly strong, as the importance of the variable was only 0.46 and 0.57 for the number of species and the number of territories, respectively (Table S2). In addition, the larger the area the greater both the number of species and territories (Tables S2 & S3).

Community composition

The pristine and restored parts had different community composition, as the effect of treatment was significant with Sørensen and Bray-Curtis indices (Table S4). Furthermore, the effect of year was significant with Bray-Curtis (Table S4), indicating that there were changes in species abundances between the sampling years 2010 and 2018 (Fig. 4). By contrast, restoration, i.e., interaction between treatment and year, had no effect on the community structure in none of the dissimilarity indices (Table S4) despite the group centroids

being somewhat closer to each other with the abundance-based Bray-Curtis metric (Fig. 4). There were no differences in the dispersion among the four groups formed by the two treatments and two sampling years measured with the Sørensen ($F_{3,36} = 0.67$, $P = 0.591$) or Bray-Curtis index ($F_{3,36} = 1.62$, $P = 0.206$).

DISCUSSION

Restoration of peatlands drained for forestry seemed to decrease the number of territories of non-specialist species during our monitoring time (6 to 13 years since restoration). By contrast, restoration did not have an effect on the number of peatland specialist bird species or the number of their territories, and restored peatlands bird communities remained different from pristine peatlands in terms of total species richness, total number of territories and community composition. These results highlight the importance of pristine peatlands for peatland specialist bird populations as current habitats, and as sources for possible future colonization of restored peatlands.

Drained parts had altogether more bird species and territories than pristine parts, both before and after restoration. This result was driven by the number of non-specialist species and their territories, and is congruent with the findings that bird diversity in peatlands may increase with disturbances (Minayeva et al. 2017). Indeed, in our study non-specialists included generalist species, such as Willow Warbler (*Phylloscopus trochilus*) and Chaffinch (*Fringilla coelebs*). These species occupy mainly forested habitats and most likely benefit from the increased tree cover in drained parts (Väisänen & Rauhala 1983). Thus, while drainage increased abundance of non-specialist species, restoration was successful in decreasing the abundance of these species back towards their natural level. Such changes should move the whole bird community composition of restored peatlands towards the community composition of pristine peatlands, and although

a subtle change of the restored parts towards their pristine counterparts was observed, it was not statistically significant in the formal community composition analysis.

The decrease of non-specialists was not balanced with an increase of peatland specialist species, which are the target of the peatland restoration actions. It is possible that the restored peatlands were not core areas of peatland species even before ditching in the 1960s. That being said, the pristine counterparts were chosen with great care to match the drained parts, and the drained parts did have less peatland specialists before the restoration took place. A possible reason for the lack of response from peatland specialists may be the still relatively short time frame of the study, although study sites had shown positive changes in hydrology, vegetation and peat formation during Boreal Peatland LIFE project (Penttinen 2015). We do acknowledge that many potentially important explanatory variables were not measured in our study, and differences in the original vegetation of restored parts may have caused some differences in the species community compositions. However, as already mentioned, the study was designed to reduce the potential for these differences by surveying control parts always next to treatment parts.

As we know surprisingly little about the detailed ecological requirements of the peatland specialist birds (Newey et al. 2016; Fraixedas et al. 2017), it is difficult to determine why they did not benefit more from restoration. Generally, peatland specialists seem to prefer openness and wetness (Järvinen & Sammalisto 1976; Väisänen et al. 1998; Fraixedas et al. 2017), but it is really not well understood what exact habitat features benefit different species. Most likely, these features are species-specific and may include, for instance, food resources (e.g. Pearce-Higgins 2010; Carroll et al. 2011; Pearce-Higgins 2011). It may well be that the restoration success in terms of water level increase may vary within the study sites (Haapalehto et al. 2014). This may result in variation in other environmental features, such as vegetation and insect fauna,

which in turn affect peatland specialist bird species. Thus, we urge future studies to measure environmental variables, such as water level, openness and vegetation structure. Incorporating these into modeling process with bird census data would help to determine how to make peatland restoration more successful for bird conservation.

However, we also note that rather than determining the detailed reasons for the community composition changes, the aim of the study was to determine whether peatland restoration as commonly implemented in Finland was effective overall in recovering the bird communities. Generally, habitat restoration can take several decades and still be incomplete (Moreno-Mateos et al. 2012; Andersen et al. 2017). Particularly in boreal peatlands, the recovery rate of peatlands is even longer than for example in tropics since ecosystem processes, e.g., water and biogeochemical cycle, in general are slower (Benayas et al. 2009). However, there are some examples of fast response to restoration. As already stated in the introduction, in United Kingdom Golden Plover benefited already after three years of restoration (Pearce-Higgins 2010; Carroll et al. 2011). In our data, there was no sign of an increasing number of Golden Plover territories (result not shown). Thus, despite of some examples of fast response to restoration, slower recovery rates seem to be more general. This underscores the need of longer time-series to assess the effectiveness of restoration on peatland biota.

We found that the number of territories of all species decreased during the study period both in pristine and restored parts. This overall decrease of territories seems to be a combination of decline of non-specialist species in restored parts, and the general declining trend of peatland specialists in pristine parts. The declining trend for peatland specialist territories may reflect the overall situation of birds using primarily peatlands as main habitats in Finland: the abundance of several of these species has declined resulting in 58% of the species to be included in the latest Red list of Finland (Lehikoinen et al. 2019). From the 16

peatland specialist species occurring in our study sites, six were included in the Red List (Lehikoinen et al. 2019). The causes of threat of these species included obviously peatland drainage for forestry and peat extraction but also other causes such as hunting (Bean goose, Eurasian curlew), water construction (Bean goose), changes in arable land (Eurasian curlew), climate change (Willow ptarmigan) as well as unknown reasons (Common snipe, Common greenshank). Moreover, the future threat factors include also changes in other countries (Bean goose, Common greenshank, Wood sandpiper). Indeed, many of the peatland specialists nesting in Finland are migratory, and they are prone to habitat loss in their over-wintering habitats and problems during migration (Berthold 2001; Sanderson et al. 2006). This exemplifies that peatland specialist species as a species group experience simultaneously multiple threats, which may hamper their ability to benefit from restoration actions. On the other hand, the general declining trend of the peatland specialist species was not clear in the restored peatlands, suggesting that perhaps restoration might help peatland specialist species to resist the general decline. Nevertheless, this trend was not significant and it was largely driven by a single pristine part in 2010 having very high number of peatland specialist's territories.

Several factors (e.g., habitat openness, cryptic bird species, size and secretive behavior of birds) might cause bias to detection rate of birds and sampling data (Emlen 1971; Bibby et al. 2000). However, territory mapping is an effective survey method for population estimates during the breeding season (Baillie 1991). Since surveys were performed during the time when birds are most active with displaying and singing, we expected the detectability to be high. The 2018 sampling spring was exceptionally warm and dry (Ilmatieteenlaitos 2019a), which could have affected the monitoring of birds and caused bias. Intra- and interspecific variation in birds singing peak, mating display and breeding (Emlen 1971; Rehm & Baldassarre 2007) depend more on warm and sunny weather than migration timing (Slagsvold 1977; Elkins 2010; Klueen et al. 2017). Hence, birds may have started breeding before the survey time, decreasing their singing and pairing activity at the time

of doing the survey (Koskimies & Väisänen 1988). Moreover, previous summers 2016 and 2017 were exceptionally cold and rainy (Ilmatieteenlaitos 2019b; Ilmatieteenlaitos 2019c). This may have had negative effects on birds breeding success in Finland, since breeding success is known to decrease in harsh weather conditions (Whitehouse et al. 2013).

In conclusion, the study showed that restoration decreased the abundance of non-specialist bird species, and that this decline was not balanced by an increase of peatland specialist species. Moreover, the general bird community composition remained different in pristine and restored peatlands six to ten years after restoration. Therefore, the recovery of the peatland bird community may take a substantially long time if it will ever recover. This underlines the importance of maintaining the remaining pristine areas undisturbed. Moreover, given the general declining trend of peatland specialist species, our results suggest that restoration actions should be implemented sooner rather than later if the decline of peatland specialist species is aimed to be halted.

ACKNOWLEDGEMENTS

We thank the Finnish Foundation for Nature Conservation, Suomen Biologian Seura Vanamo ry, Societas pro Fauna et Flora Fennica and Keski-Suomen lintutieteellinen yhdistys ry (KSLY) for funding the project during 2018 (for TA), and Kone Foundation (for ME). We are also thankful for Metsähallitus and ELY Centre for Central Finland for collaboration as well as the people helping with data collection.

FIGURE LEGENDS

Fig. 1 Map of the study sites, including restored and pristine parts (n=11).

Fig. 2 Picture from a restored part of a study site (A) and a pristine part of a study site (B).

Fig. 3 Number of species (a,b,c) and number of territories (d,e,f) of all species (a,d), peatland specialist species (b,e) and non-specialists (c,f) in pristine and restored parts of the study sites (n=11). The lines are fitted general linear models.

Fig. 4 A non-metric multidimensional scaling plot describing the bird community in drained (black symbols) and pristine (open symbols) before (circles) and after (triangles) restoration using the Bray-Curtis dissimilarity index (n=10). PcoA 1 and PcoA 2 are principal component axes 1 and 2. The legend for each group (pristine parts, sampling year 2010; pristine parts, sampling year 2018; drained parts, sampling year 2010; restored parts, sampling year 2018) is located in the group centroid.
