Weight Status and Mental Well-Being Among Adolescents: The Mediating Role of Self-Perceived Body Weight. A Cross-National Survey

Anne-Siri Fismen, Martina Galler, Knut-Inge Klepp, Angeline Chatelan, Caroline Residori, Kristiina Ojala, Anna Dzielska, Colette Kelly, Marina Melkumova, Sanja Music Milanovic, Paola Nardone, Eliska Stefanová, Gerd Flodgren, Therese Bakke, Oya Ercan, Oddrun Samdal, and Arnfinn Helleve

ABSTRACT

Background: Adolescents' overweight and obesity are associated with poor mental health. However, little is known whether the influence of overweight and obesity on mental well-being is influenced by self-perceived body weight. Exploring underlying mechanisms behind the relationships between obesity and mental well-being is of interest for policy makers and others working in the field of adolescent health.

Methods The study is based on national representative data from adolescents (15 y) participating in the 2017/2018 Health Behaviour in School-aged Children study (47 countries, n = 76998). Mixed regression models including gender and socio-economic status as covariates were used to analyze associations between weight status and mental well-being (life satisfaction and subjective health complaints) and to explore the mediating effect of self-perceived body weight (feeling too thin or too fat). Country differences were further assessed by multiple factor analysis.

Results: Self-perceived body weight mediated the observed associations between overweight, obesity and mental well-being. Perceiving own body weight as "too thin" or "too fat" was associated with lower mental well-being, regardless of weight status. Self-perceived body weight varied by gender, socio-economic status and country.

Discussion: Self-perceived body weight may, to a greater extent than BMI, explain the variation in mental well-being among adolescents. The results are important to policy makers, clinicians and others targeting adolescents' health.

Implications and contribution statement: The present results should be considered when developing policy actions aiming to regulate external pressure related to body weight. Fostering appreciation of the body in relation to its functionality instead of size and shape may improve young people's mental well-being.

Keywords: Weight status; Self-perceived body weight; Mental well-being; Adolescents

Introduction

Overweight and obesity are considered important determinants of poor mental health in the adolescent population. Previous studies report on associations between overweight and obesity and mental illness (1) as well as subjective mental health (2). Self-perceived weight perception is suggested to explain why higher BMI tends to be associated with poor mental health (3). However, few studies have focused on associations between weight status, self-perceived weight and positive mental health, e.g., mental well-being in the adolescent population. The decline in adolescent mental well-being observed in many countries over the last decades (4) has developed in the context of high and even increasing prevalence of overweight, obesity (5) and weight reduction behaviours (6). Addressing associations between young people's weight status, mental well-being and underlying pathways is thus relevant for clinicians and public health professionals.

Mental well-being is a non-clinical measure of positive mental health and a fundamental component of World Health Organization (WHO)'s definition of health (7). Mental well-being is associated with self-rated health (8), perceived stress and anxiety (9), but is not a proxy of mental illness. It encompasses a more global dimension of people's psychological well-being (10). Good mental well-being during younger years is critical to ensuring healthy transitions to adulthood, with implications for overall well-being, growth and development (5), and thus an important health issue. Concern is devoted to the observed declines in adolescent mental well-being during the last two decades, which has developed in the context of increased prevalence of overweight and obesity (5). Examining the associations between weight status and mental well-being may provide a broader understanding of adolescent health with important implications for policy and practice.

Mental well-being can be measured by indicators of life satisfaction and subjective health complains (4, 5). Lower life satisfaction is reported among people living with overweight and obesity compared to normal weight, in different age groups (12) including adolescents (13). The possible link between subjective health complaints, weight status is so far understudied. However, subjective health complaints are inversely associated with physical activity levels and healthy food habits (14), both correlates of overweight and obesity. The impact of weight status on mental well-being are highlighted also in studies showing that youths living with obesity report lower quality of life than do their counterparts with cardiac conditions, diabetes and gastrointestinal conditions (15), and at the same level as those with cancer (16). These findings reflect that living with overweight and obesity may have a significant impact on young people's lifes and suggest a link between weight status and mental well-being, either directly through BMI or through other associated health issues. In the project "Confronting obesity: Co-creating policy with youth", in which adolescents' views on the drivers of obesity are identified (17), adolescents strongly emphasised perception of own body weight as an important factor in the relationship between weight status and mental health. An Iranian study (13) suggested that self-perceived overweight was a stronger predictor of life satisfaction than was actual weight and hypothesized that self-perceived weight may be a mediator in the relationship between BMI and mental well-being. Similarly, a Germany study (18) suggested that adolescent's weight perceptions, rather than actual weight, were associated with personal resources such as self-esteem, self-efficacy, optimism, and sense of coherence. However, evidence for associations in cross-national population-based samples are limited. A research gap of particular interest is whether associations between weight status, self-perceived body weight and mental well-being are generic phenomena or determined by gender, socioeconomic status (SES) or other sociocultural differences. Adolescents' weight status and mental health varies by gender, country and SES (5), and studies exploring these relationships, including mediating factors, may be useful for policymakers, adolescent health service providers and others working in the field of adolescent health.

The present study aims to explore associations between weight status (assessed by BMI-z-score for age and sex) and mental well-being (life satisfaction and subjective health complaints), with a particular focus on the mediating role of self-perceived body weight, and differences related to gender, SES and country, in national representative samples of 15-year-olds from 47 countries participating in the Health Behaviour in School-aged Children study

(HBSC) 2017/2018. To the best of our knowledge, this is the first time such associations are studied in a large, cross-national sample of adolescents.

Methods

The study is based on national representative data from the HBSC study, a World Health Organization (WHO) collaborative cross-national study, with an overall aim to generate increased understanding of health and health behaviour, and their context in the lives of young people aged 11, 13 and 15 years (5). For this paper, in order to reduce complexity, we considered samples of only 15-year-old students from 47 countries/regions, collected in the school year 2017/2018. The primary sampling unit was the school class or, in some countries, the school. The students answered an internationally standardized questionnaire at school after receiving instructions from their teacher. Oral and written information on the confidentiality of their responses were provided and participation was anonymous and voluntary. School and student's response rates varied between the countries. Schools/classes that declined to participate, as well as students absent on the day the survey was carried out, were the two main sources of non-response and were not followed up. Ethical consent from the institutional ethics committee(s) or any relevant board at country level was required. Informed consent of parents (guardians) and adolescents participating in the study was required in the majority of countries included (a minority of countries used informed passive consent). Researchers followed the standardised international research protocol to ensure consistency in survey instruments, data collection and processing procedures. The HBSC Data Management Centre checked the quality of the data collected, performed appropriate cleaning of the data and merged national data sets into an international data file. Detailed information about the study is available at www.hbsc.org.

Measures

Weight status was based on self-reported weight and height measured by the questions: "How much do you weigh without clothes?" and "How tall are you without shoes?" BMI (in kg/m^2) was calculated and classified into "thinness", "normal weight", "overweight" and "obesity" based on the international standardized age- and sex-specific cut off points proposed by Cole and Lobstein (20) for the International Obesity Task Force. Self-reported BMI is considered a reliable proxy measure across age, sex and race/ethnicity subpopulations of adolescents (21). Implausible values were identified as system missing data by The HBSC Data Management Centre.

Self-perceived body weight, the subjective interpretation of an individual's weight status, was measured by the following measure: "Do you think your body is...? "Much too thin", "A bit too thin", "About the right size", "A bit too fat", "Much too fat". This item was developed by the HBSC study and has shown good test–retest stability (ICC = 0.81; 95% CI = 0.76–0.85) (22). Similar questions have been used in several other health-related questionnaires of proven validity (23). For the presented study, responses were recoded into three categories: "too thin"," about the right size", and "too fat". Norway and Macedonia used different response categories and were therefore excluded from the respective analyses.

Life satisfaction is defined as "A cognitive global judgement of one's life as a whole" (10). Participants rated their life satisfaction in a single item question referred to as the Cantril Ladder (24): "Here is a picture of a ladder. The top of the ladder "10" is the best possible life for you and the bottom "0" is the worst possible life for you. In general, where on the ladder do you feel you stand at the moment?" The Cantril Ladder has shown good reliability and convergent validity among adolescents (25).

Subjective health complaints is a subjective measure of complaints that may have both psychological and somatic origins, with higher prevalence of complaints associated with psychological than somatic health (26). Based on the HBSC Symptom Checklist (HBSC-SHC), the adolescents were asked how often they experienced the following symptoms over the last six months: headache, abdominal pain, backache, feeling low, irritability or in a bad mood, feeling nervous, sleeping difficulties and dizziness. The five response categories were: "About every day", "More than once a week", "About every week", "About every month" and "Rarely or never". The HBSC-SCL has adequate test-retest reliability and validity properties (27). For the presented study, the average of the sum score was used ranging from 1 (all eight symptoms about every day) to 5 (rarely or never any symptoms). Data on subjective health complaints were not available in the Macedonian sample and therefore excluded from the analysis of subjective health complaints.

Socioeconomic status was assessed using the family affluence scale (FAS) (28). FAS is a measure of material affluence derived from the characteristics of the family's household and consists of six items. The individual FAS responses were combined and standardized by using ridit transformation to give a linear SES-score (0–1) within each country with an overall mean

score of 0.5. The scores where then categorized in lowest 20%, middle 60 % and highest 20% within each country.

In the total sample, 16.6% had missing data on BMI and were excluded from the analysis. In the remaining sample, the percentage of missing data were as follows: self-perceived body weight 1.2%, life satisfaction 1.5%, subjective health complaints 2.5% and SES 4%.

Statistics

Mixed linear regression models (for the total sample as well as for each country included) were used to assess the relationship between weight status, gender and SES as independent variables and mental well-being indicators (i.e., life satisfaction and subjective health complaints) as dependent variables (model 1). Self-perceived body weight was included in a second model (model 2).

Mixed logistic regression models were used to assess the relationship between weight status, gender and SES as independent variables and self-perceived body weight ("feeling too thin" as well as "feeling too fat") as dependent variables. In all mixed models, country and school class nested in country were included as random effect variables.

Formal testing of the categorical mediator (self-perceived weight) was performed as suggested by Iacobucci (29). As the independent variable (weight status) was multi-categorical variable, mediation was estimated for the relevant paths separately (30) using indicator coding with "normal weight" as base level for weight status and "about right size" as base level for self-perceived body weight. $z_{Mediation}$ score was calculated based on the parameters, illustrated in Fig 1; path **c** was estimated by Model 1 (Table 2), path **b** and **c'** were estimated by Model 2 (Table 2), path **a** was estimated by Model 3 (Supplementary Table 2) Statistical analysis was performed in R, version 4.0.4 (nlme package for mixed linear regression models, lme4 and emmeans for mixed logistic regression models.

Results

In the current study population (N = 64229) 51.4 % were girls, the median age was 15.5 years. Country specific sample characteristics and descriptive statistics are shown in Table 1.

Table 1

Weight status, self-perceived body weight and mental well-being

Associations between weight status and mental well-being are shown in Table 2; model 1a for life satisfaction, model 1b for subjective health complaints. The intercepts estimate mental well-being among boys classified with normal weight and high SES (life satisfaction β=8.04, 95%CI 7.93, 8.15; subjective health complaints β=4.05, 95%CI 3.99, 4.11). Living with overweight and obesity, but not thinness, were associated with lower scores for both indicators of mental well-being, obesity having a larger negative effect (life satisfaction β=-0.47, 95%CI -0.55, -0.38; subjective health complaints β=-0.16, 95%CI -0.2, -0.12) than overweight (life satisfaction β=-0.18, 95%CI -0.22, -0.13; subjective health complaints β=-0.09, 95%CI -0.11, -0.07). Being a girl, as well as having medium or low SES, were also associated with lower scores for both indicators of mental well-being.

When self-perceived body weight was included (model 2), the negative association between overweight, obesity and mental well-being observed in model 1, was no longer present: no significant association were identified between living with obesity and mental well-being, and slightly positive associations were seen between overweight and mental well-being. Perceiving own body weight as "too fat" and "too thin" were negatively associated with both

indicators of mental well-being; feeling "too fat" having a larger negative effect (life satisfaction β=-0.73, 95%CI -0.76, -0.69; subjective health complaints β=-0.34 95%CI -0.35, -0.32) than feeling "too thin" (life satisfaction β=-0.36,95%CI -0.40, -0.32, subjective health complaints β=-0.19,95%CI -0.21, -0.17). Country specific estimates for these associations are presented in Supplementary Table 1, reporting that living with overweight or obesity was associated with lower scores at mental well-being in half of the countries, self-perceived weight was associated with mental well-being in the absolute majority of the countries examined.

Table 2

Mixed linear regression analysis of mental well-being, a) life satisfaction (0-10), b) subjective health complaints (1-5, 1 = all symptoms frequently, 5 = all symptoms never or rarely) as independent variables and fixed dependent variables: weight status (with "normal weight" as base level), gender ("boys" as base level), SES ("highest 20%" as base level) in model 1 and self-perceived body weight ("about right size" as base level) added in model 2.

	Too thin				-0.19	[-0.21, -0.17]	**<0.001**
	Too fat				-0.34	[-0.35, -0.32]	**<0.001**

* Life satisfaction: 0=worst possible, 10=best possible
** Subjective health complaints: 1=all symptoms frequently, 5=all symptoms never or rarely
SES: Socioeconomic status
CI: Confidence interval

As shown in Table 3, all mediation paths (Fig 1) were significant. Based on these results, as well as the results presented in Table 2, self-perceived body weight was confirmed as a mediator in the relationship between weight status and mental well-being.

*Bonferroni correction for multiple testing: $\alpha = 0.017$

Y, X and M refers to the mediation model presented in Figure 1

As shown in Table 4, adolescents who perceived themselves as "too fat" were more likely to live with overweight (OR 9.06, 95%CI 8.44, 9.73) and obesity (OR 32.64, 95%CI 27.5, 38,68) than with normal weight, while those who perceived themselves as "too thin" were more likely to live with thinness (OR 6.69 95%CI 6.23, 7.19). Girls with normal BMI were more likely to feel "too fat" (OR 3.16, 95%CI 3.02,3.31) and less likely to feel "too thin" (OR 0.38, 95%CI 0.36,0.40) than were boys. Low SES was associated with feeling "too fat" (OR 1.11, 95%CI 1.03,1.20) as well as "too thin" (OR 1.13, 95%CI 1,03.1,22).

Table 4

Logistic regression analysis of self-perceived body weight dissatisfaction, a) "feeling too fat" b) "feeling too thin" as independent binary variables and fixed dependent variables: weight status (with "normal weight" as base level), gender ("boys" as base level), SES ("highest 20%" as base level).

Discussion

The study suggests that associations between overweight, obesity and mental well-being can be explained by self-perceived body weight. Moreover, perceiving own body weight as "too thin" or "too fat" was associated with lower mental well-being, regardless of weight status, and associated with gender, SES and cross-country differences.

Weight status, self-perceived body weight and mental well-being

Adolescents living with overweight and obesity reported lower mental well-being than did their counterparts with normal weight. Self-perceived body weight was confirmed as a mediator in this relationship, suggesting that the psychological perception of being "too fat" explains the observed associations between overweight, obesity and mental well-being. The findings complement other studies in which high BMI was linked to lower levels of mental well-being (31-34), although these did not adjust for self-perceived body weight. Of note, one other study (13) found that the associations between overweight, obesity, and life satisfaction disappeared after adjusting for self-perceived weight, which is in line with our results. Likewise, the findings correspond with a systematic review of overweight, self-perceived weight and depressive symptoms, in which overweight was no longer associated with depressive symptoms after adding weight perception to the predictive model (2). The present

results add to the literature suggesting are that self-perceived weight is a predictor of mental health outcomes (2, 3, 18, 19)

It is conceivable that self-perceived body weight may lie on the causal pathway between weight status and mental well-being, playing a mediating role. However, the current study is based on cross-sectional data which limit the interference of causal relationships, and reverse causation may exist. Poor mental well-being may be a consequence of perceived overweight but also a predictor of weight gain (35). Furthermore, the study is based on self-reported data and the mediation effect may to some extent be explained by shared variance caused by responding bias (e.g., adolescents who rate their well-being lower may also rate their body weight more critically). Reverse causality may also play a role, as adolescents reporting lower well-being may judge their weight more critically. Also potential third confounding variables should be considered; depression symptoms may explain the link between perceived weight and well-being scores, as could perceived weight discrimination explain the link between self-perceived weight and mental well-being scores, as perceived weight discrimination is associated with higher odds of self-perceived overweight higher and poorer mental well-being (2).

Perceiving own body weight as "too thin" and "too fat" were associated with lower mental well-being, regardless of weight status, with the lowest scores among those perceived themselves as "too fat". The findings correspond with other studies (13, 36)(2). Feeling "too thin" or "too fat" may result in a myriad of psychological and emotional effects which may influence mental well-being. Feeling "too fat" may trigger social rejection concerns as internalisation of weight stigma, which may lead to physiological distress (2) and lower mental well-being, as well as weight reduction behavior (6). The relationship between self-perceived weight and mental well-being may furthermore be viewed in light of developmental changes, including onset of puberty, which may demand a constant restructuring of the adolescent's perception of their body which is important in the development of one's self-concept, self-esteem and interpersonal relationships with peers (37).

Girls seems to be vulnerable when it comes to processes related to body weight and mental well-being, maybe because of strong external body related pressures (38). The observed gender differences in self-perceived weight may reflect that girls tend to internalize a thin body ideal, while boys' ideals are geared towards muscularity (39). For boys, it is likely that

both obesity and lack of muscularity are of importance for how they perceive their weight. This should be followed up in future studies, as an increasingly number of boys engage in weight reduction behaviours (6). It should be noted however, that feeling "too thin" or "too fat" may be a sign of mental illness (e.g., eating disorders), which should be followed up in future studies. Furthermore, low SES appeared as a significant co-variate in the present analysis, indicating that socioeconomic resources may play a role in both weight perception as well as in fostering mental health in the younger population. This perspective should be further investigated.

Country differences

Country differences in the associations between weight status, self-perceived body weight and mental well-being may reflect that both sociocultural influence (e.g., social media, family, peers) and social weight comparisons play a role in weight perceptions and its influence of mental well-being. Overall, stronger associations between self-perceived weight and mental well-being were observed in countries with high prevalence of adolescents feeling "too fat" or "too thin". High prevalence of feeling "too fat" might reflect sociocultural focus and external pressure on a thin body ideal accompanied by negative stereotyping of overweight and obesity, and the importance of relative comparisons. Moreover, in countries with high prevalence of overweight/obesity, higher weight may be perceived as normal weight in terms of social body weight comparisons. These perspectives may be followed up with qualitative studies.

Implications

The findings that one in two adolescents perceived themselves as "too thin" or "too fat" is of great public health concern. Although this percentage has been relative stable in recent years, the associations between self-perceived body weight and mental well-being has changed; adolescents who perceived themselves as "too fat" have become increasingly likely to report lower mental well-being, relative to those perceiving their body weight as "about the right size" (41). Mental well-being has worsened in many countries recent years (5) which may be due to changes in associations between self-perceived weight and mental well-being (41).

Reducing overweight/obesity are stated as key public health priorities. However, the use of BMI as an indicator of normal or healthy weight is associated with challenges. While public

health professionals are concerned about the obesogenic environment, health psychologists and health promoters worry about the societal pressure for thinness. Concerns have been raised about potential negative psychological effects created by interventions addressing weight loss largely focusing on body shape and size, and of the extensive media coverage targeting individual level obesity measures Alternatively, fostering appreciation of the body in relation to its functionality as opposed to its appearance may encourage adolescents to feel positive about their bodies and at the same time engage in healthy behaviours (42). These implications are relevant for clinicians working with adolescents of all body weight and sizes, and adds to the work by Golding (43), in which is suggested that clinicians should assess weight perceptions more consistently and considering feeling "too thin" and "too fat" to be risk factors for poor mental well-being.

Social media may be of particular importance for development of young people's weight and size perception, and social media campaigns should consider image-related content in order to avoid heighten body weight dissatisfaction. Commercials for products promising weight reduction and larger muscles are commonly communicated to adolescents through social media, as are advertisements for cosmetic and plastic surgery. These perspectives are important when developing policy actions aiming to regulate external pressure related to body weight.

Strengths and limitations

Important strengths of the present study are the large dataset based on nationally representative sampling and the use of standardized measurements in all countries. The limitations include the use of self-reported height and weight, which may result in misclassification of BMI, but are considered valid measures for population studies (21) , due to underestimation of weight among both genders and overestimation of height among boys. Another possible limitation is that the perception of one's body weight may change considerably during adolescence, and associations between BMI, self-perceived body weight, and mental well-being might differ between age groups. Including another age group may have produced different results. Finally, race and ethnicity could potentially be important covariates. Unfortunately, these perspectives could not be assessed in the present study because of lack of adequate data within the study.

Conclusion

The present study suggests that associations between overweight and obesity and mental well-

being can be explained by self-perceived body weight. Perceiving own body weight as "too fat" was significantly associated with gender, SES and country, all of which contributed to explaining the variance of in the mental well-being of adolescents included in this study. Further research is needed to understand these relationships better and to develop effective intervention strategies.
