(Received 4 May 2020; accepted 6 August 2020; published 31 August 2020)

In any natural science, measurements are the essential link between theory and observable reality. Is it possible to obtain accurate and relevant information via measurement whose action on the probed system is unknown? In other words, can one be convinced to know something about the nature without knowing in detail how the information was obtained? In this paper, we show that the answer is, surprisingly, yes. We construct and experimentally implement a quantum optical probing measurement where measurements on the probes, i.e., the photons' polarization states, are used to extract information on the systems, i.e., the frequency spectra of the same photons. Unlike the preexisting probing protocols, our measurement does not require any knowledge of the interaction between the probe and the system.

DOI: [10.1103/PhysRevA.102.022232](https://doi.org/10.1103/PhysRevA.102.022232)**I. INTRODUCTION**

As a necessary part of any natural science, measurements lie at the heart of understanding the observable universe. They are needed both to test the existing theories and to inspire new branches of theoretical research. In addition to purely scientific purposes, measurements are also necessary for technological applications. More specifically, the readout of the outcome of a quantum computer or quantum simulator is extracted by measuring the system acting as the information carrier. Sometimes, measurements are also needed to monitor the performance of the device while it is running.

Despite their useful purposes, measurements also have harmful effects. Every nontrivial measurement disturbs the system state [1–3]. In some cases, direct measurement may even destroy the whole system of interest. To avoid this problem, so-called nondemolition [4,5] and quantum probing measurements have been proposed and experimentally implemented [6–10]. In a quantum probing measurement, the idea is to avoid directly measuring the system of interest by coupling it to a disposable *probe system* instead. The system-probe coupling causes the probe state to change and, from the change, one can deduce how the system of interest was before the coupling [11–13]. The existing protocols are heavily based on fully knowing the system-probe coupling, and implementation of such protocols requires faithful experimental realization of that specific coupling. As any experimental implementation has its limitations, the coupling is never perfectly known or controlled.

In addition to the above-mentioned quantum probing schemes, it is also worth mentioning here the recent

developments in quantum hypothesis testing; see, e.g., [14–16]. The motivating question—for hypothesis testing—is which one of the *a priori* introduced hypotheses is consistent with the obtained measurement data. For example, in the open system context, it is possible to test which one of the possible Rabi frequencies was actually used to drive a two-level system [14]. Moreover, hypothesis testing also has applications, e.g., in quantum illumination [17], to check whether a low-reflectivity object existed—or not—in a given target region [15,16]. For quantum probing, the starting point is slightly different. Here, the aim, in the best case, is to obtain a precise quantitative value—with bounds and without *prior* information or hypotheses—on a property of a given degree of freedom while measuring another degree of freedom.

In [18], a new approach to quantum probing was proposed. These protocols are based on the properties of so-called α fidelities, which were shown to satisfy a generalized data-processing inequality which was found useful for multiple purposes [18]. The inequality was applied to study the Hilbert space dimension of the programmable quantum processor in approximate implementation of quantum channels, and to make predictions of unsolvable quantum dynamics. Interestingly, it was also shown to allow one to construct probing measurements without knowing anything about the system-probe coupling. In this sense, the protocol should give accurate information even though it is impossible to know how the measurement actually happens.

In this paper, we present an experimental implementation of such probing measurement. Our system of interest is the frequency degree of freedom of a single photon and our probe is the polarization of the same photon. This system has attracted a lot of attention lately [19–27]. We show how measuring two polarization states before and after their interaction with the frequency can be used to extract upper

*henri.s.lyyra@jyu.fi

bounds for the width of the corresponding frequency spectra. We demonstrate how the protocol works even in cases where the coupling is unknown. As a trade-off of performing the probing without knowing the system-probe coupling, we need to perform full tomography for the probe system. Our measurement data do not yield to estimate for the exact value of the unknown parameter, but instead we obtain upper or lower bounds, derived analytically from the generalized data-processing inequality.

The paper is structured as follows: In Sec. II, we briefly discuss the open quantum system picture, the α fidelities, and the generalized data-processing inequality. In Sec. III, we present our photonic system and apply the generalized data-processing inequality to derive the bounds for the unknown width to be determined by the probing measurement. In Sec. IV, we present the experimental setup and the measurement results. Finally, in Sec. V, we summarize our results and discuss future aspects.

II. OPEN QUANTUM SYSTEMS, QUANTUM PROBING, AND α FIDELITIES

We say that a quantum system A is open if it interacts with some other system B , the environment. Commonly, it is assumed that A and B are uncorrelated before the dynamics begins. In the dynamics, the total state of the combined system AB undergoes a change, described by a unitary U . The evolved state of system A can be solved as

$$\Phi(\rho) = \text{tr}_B[U(\rho \otimes \xi)U^\dagger], \quad (1)$$

where ρ and ξ are the initial states of systems A and B , respectively, and $\text{tr}_B[X]$ is the partial trace of X over the Hilbert space of B [11–13]. By this construction, Φ is a completely positive and trace-preserving (CPTP) map or, in other words, a *channel*. The effects of CPTP maps have been widely studied and it has been shown that information in terms of trace distance [28] and quantum entanglement can only be lost in (local) CPTP transformations [29], and fidelity between two states can never decrease [28]. For trace distance and fidelity, this means that they satisfy data-processing inequalities.

Despite its harmful effects, open system dynamics can also be useful. One of its applications is the *quantum probing* measurements. In quantum probing, the goal is to obtain information of some property of the system S without directly measuring it. This can be the case when S is a part of a device, such as a quantum computer or a quantum simulator, and one wants to monitor the device without having to stop it to perform a measurement. In quantum probing, S is unitarily coupled to a disposable probe system P and measurements on the evolved probe are used to gain information about S . In the above description of open quantum system dynamics, the system of interest S corresponds to the environment B and the probe P is the open system A . Commonly, the probing protocols rely on knowing the coupling U and they are based on the solvable connection between the unknown parameters of S and the channel Φ of P , caused by the interaction, as in Fig. 1.

On the other hand, if the coupling U is not known, the unknown parameters of S cannot be mapped to the transformation Φ of the probe state. Consequently, the traditional

FIG. 1. The common quantum probing approach. The system S and the probe P interact under the unitary coupling U . After the interaction, measurements on P in the evolved state $\Phi(\rho)$ are used to determine unknown properties of S . Here, U is known and the unknown parameters of ξ are mapped to the state transformation $\rho \mapsto \Phi(\rho)$ of P .

probing approach cannot be applied. To see how the quantum probing can be performed in such situation, let us consider the two cases in Fig. 2. When the coupling U has been fixed, the dynamics of the probe P depends on the initial state ξ of the system S . As a consequence, preparing S in different states ξ_1 and ξ_2 and coupling it to P can induce different channels Φ_1 and Φ_2 to P , even if the coupling U is the same in both cases.

This observation was exploited in [18] to form a mathematical tool for studying open quantum systems based on

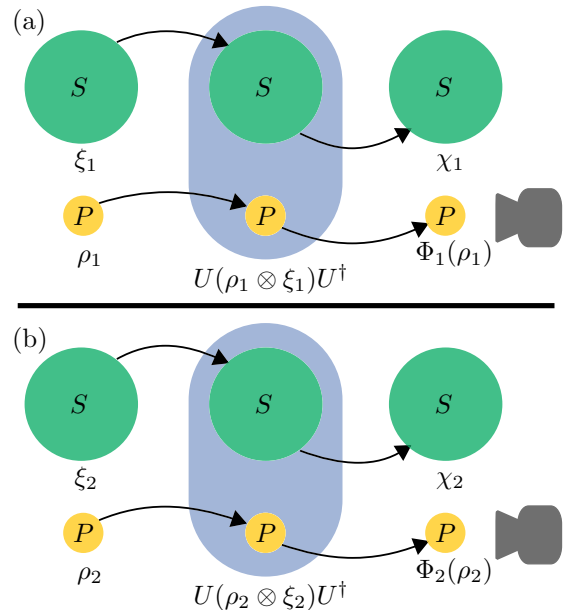

FIG. 2. The unknown coupling quantum probing approach. The system S interacts with the probe P . In cases (a) and (b), the unitary coupling U between S and P is the same. The unknown parameter in the system states ξ_1 and ξ_2 is the same, but some control parameter is different. As a consequence, the induced probe channels Φ_1 and Φ_2 may be different. Even though the coupling U is unknown, and consequently so are the channels Φ_1 and Φ_2 , comparison of the measured probe states $\Phi_1(\rho_1)$ and $\Phi_2(\rho_2)$ can be used to gain accurate information on the unknown parameter.

the comparison between the initial environment states and the channels they induce. The α fidelity of states was defined for $\alpha \in (0, 1)$ as [18]

$$F_\alpha(\rho_1, \rho_2) := \text{tr}\left[\left(\rho_2^{\frac{1-\alpha}{2\alpha}} \rho_1 \rho_2^{\frac{1-\alpha}{2\alpha}}\right)^\alpha\right]. \quad (2)$$

In the special case $\alpha = 1/2$, we note that $F_{1/2}$ is the commonly used fidelity of states.

Now, let us consider the α fidelities in the context of Fig. 2. The unitary coupling U between P and S is fixed, but in Figs. 2(a) and 2(b), the initial states of P and S can be different. Thus, different choices of states ξ_1 and ξ_2 of S induce channels Φ_1 and Φ_2 to P in the interaction, respectively. In this open system picture, it was shown that the α fidelities satisfy the following inequality:

$$F_\alpha(\rho_1, \rho_2)F_\alpha(\xi_1, \xi_2) \leq F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2)), \quad (3)$$

for all $\alpha \in [1/2, 1)$ [18]. It is worth noting that Eq. (3) does not explicitly depend on the coupling U , so it gives a fundamental bound for the relation of the channels Φ_1 and Φ_2 that two states ξ_1 and ξ_2 can induce. Conversely, it sets restrictions to the states ξ_1 and ξ_2 that can induce two given channels Φ_1 and Φ_2 . This property makes it useful for different applications. Equation (3) can also be interpreted as a generalization of the data-processing inequality $F_{1/2}(\rho_1, \rho_2) \leq F_{1/2}(\Phi(\rho_1), \Phi(\rho_2))$ of the common fidelity function by adding the freedom of parameter for $\alpha \in [1/2, 1)$, giving us $F_\alpha(\rho_1, \rho_2) \leq F_\alpha(\Phi(\rho_1), \Phi(\rho_2))$, and even further to the case of different channels Φ_1 and Φ_2 , as in Eq. (3).

Interestingly, Eq. (3) allows us to construct quantum probing protocols with no knowledge of the coupling in the following way: Assume that S is prepared in the state $\xi(x, y)$ and our task is to extract information of the value of parameter x , and y is some controllable parameter. The experimenter has control over the initial state of P and the parameter y . By preparing P in some known states ρ_1 and ρ_2 , and evolving them with the channels Φ_1 and Φ_2 , induced by states $\xi(x, y_1)$ and $\xi(x, y_2)$ of S , respectively, the experimenter obtains the values of $F_\alpha(\rho_1, \rho_2)$ and $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2))$. When the x and y dependence of $\xi(x, y)$ is known, different values of x can be numerically tested in $F_\alpha(\xi(x, y_1), \xi(x, y_2))$. The values of x which cause violation of Eq. (3) are immediately known to be incorrect and bounds of the actual value of x can be obtained. In cases where $F_\alpha(\xi(x, y_1), \xi(x, y_2))$ is bijective in terms of x , analytical bounds for the unknown x can be derived as functions of $F_\alpha(\rho_1, \rho_2)$, $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2))$, y_1 , and y_2 .

Next, we construct and analyze such a protocol by fixing the system and probe, and then we implement the probing protocol in an all-optical experiment.

III. THE PHOTONIC SYSTEM AND PROBING

Our system of interest is the frequency degree of freedom of a single photon. We assume that the central frequency μ of Gaussian intensity distribution $|g(\omega)|^2$ can be shifted in a controlled way. Instead, the standard deviation σ is unknown and our goal is to get information about it. The frequency states are given by

$$\xi_k = \int |g_k(\omega)|^2 |\omega\rangle\langle\omega| d\omega, \quad (4)$$

FIG. 3. Illustration of the frequency states ξ_1 and ξ_2 . The standard deviation σ is the same in both Gaussian distributions $|g_1(\omega)|^2$ and $|g_2(\omega)|^2$, and it is the unknown parameter of our interest. In the probing protocol, we control the difference between central frequencies $\Delta\mu = |\mu_2 - \mu_1|$, and thus it is known.

where

$$|g_k(\omega)|^2 = \frac{1}{\sqrt{2\pi}\sigma^2} e^{-\frac{(\omega-\mu_k)^2}{2\sigma^2}}, \quad k \in \{1, 2\}, \quad (5)$$

σ is the unknown standard deviation, and μ_k is the mean or central frequency of the Gaussian distribution $|g_k(\omega)|^2$, as illustrated in Fig. 3. Here, ω are the frequency values with amplitudes $g_k(\omega)$.

Now, the α fidelity between two frequency states becomes

$$F_\alpha(\xi_1, \xi_2) = e^{-(1-\alpha)\alpha\frac{\Delta\mu^2}{2\sigma^2}}, \quad (6)$$

where we have denoted $\Delta\mu = |\mu_2 - \mu_1|$. In the experiment, $\Delta\mu$ is our known controllable parameter. We note that $F_\alpha(\xi_1, \xi_2)$ is monotonically increasing in σ and α , and monotonically decreasing in $\Delta\mu$ when $\alpha \in [1/2, 1)$. In this optical setup, our probe is the polarization qubit of the photon.

Now, we consider what kinds of bounds can be derived from Eq. (3) for the three cases $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2)) < F_\alpha(\rho_1, \rho_2)$, $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2)) = F_\alpha(\rho_1, \rho_2)$, and $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2)) > F_\alpha(\rho_1, \rho_2)$. First, assuming $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2)) < F_\alpha(\rho_1, \rho_2)$, $\Delta\mu > 0$, and using the initial system states of Eq. (4), Eq. (3) yields to

$$\sigma \leq B_1(\alpha) := \sqrt{\frac{\alpha(\alpha-1)\Delta\mu^2}{2\ln[F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2))/F_\alpha(\rho_1, \rho_2)]}}. \quad (7)$$

Thus, measuring $\Phi_1(\rho_1)$ and $\Phi_2(\rho_2)$ results directly to an α parametrized family of upper bounds for the unknown standard deviation σ . We note that in our case, $F_\alpha(\xi_1, \xi_2) = F_\alpha(\xi_2, \xi_1)$, but generally F_α is not symmetric with respect to the inputs, namely, $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2)) \neq F_\alpha(\Phi_2(\rho_2), \Phi_1(\rho_1))$ and $F_\alpha(\rho_1, \rho_2) \neq F_\alpha(\rho_2, \rho_1)$. As a consequence, the same measurement data give us an additional

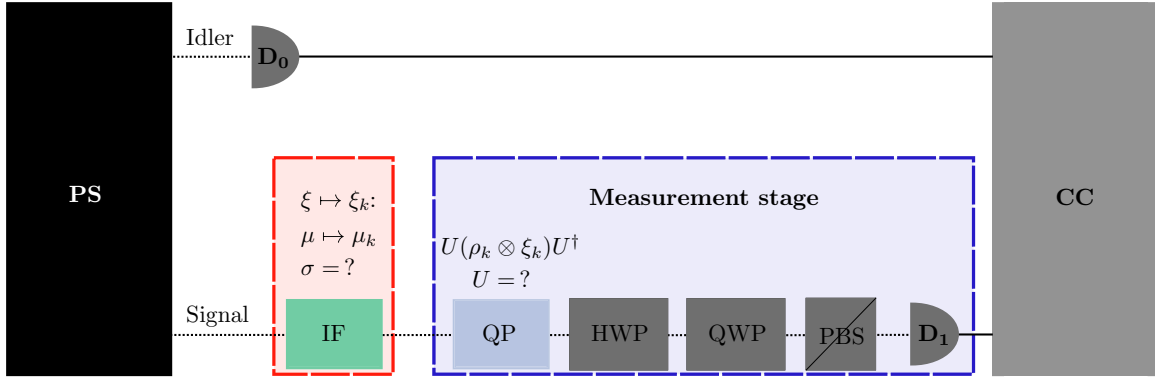

FIG. 4. The experimental setup. The photon source (PS) produces a pair of photons. The signal photons' polarization state is prepared at PS to $|+\rangle\langle+|$ by passing it through a polarizer fixed to 45 degree angle with respect to the \leftrightarrow axis. The idler photon is detected with the single-photon detector D_0 , which triggers the coincidence counting electronics (CC) to wait for the signal photon to arrive at detector D_1 . After PS, the central frequency μ of the signal photon can be adjusted by tilting the interference filter (IF). After the state preparation, the signal photon goes to the probing measurement stage. First, frequency (the system) is coupled with polarization (the probe) when the photon goes through quartz plates (QP). After the interaction, the evolved state $\Phi(\rho)$ of the polarization qubit (probe) is determined by performing a tomographic measurement with a combination of a half-wave plate (HWP), quarter-wave plate (QWP), and a polarizing beam splitter (PBS).

family of bounds:

$$\sigma \leq B_2(\alpha) := \sqrt{\frac{\alpha(\alpha-1)\Delta\mu^2}{2\ln[F_\alpha(\Phi_2(\rho_2), \Phi_1(\rho_1))/F_\alpha(\rho_2, \rho_1)]}}. \quad (8)$$

On the other hand, if $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2)) = F_\alpha(\rho_1, \rho_2)$ or $\Delta\mu = 0$, the initial system states of Eq. (4) in Eq. (3) lead to the trivial condition $\sigma \geq 0$. Lastly, assuming $F_\alpha(\rho_1, \rho_2) < F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2))$, $\Delta\mu > 0$, and using the initial system states of Eq. (4) in Eq. (3) gives us

$$\sigma^2 \geq \frac{\alpha(\alpha-1)\Delta\mu^2}{2\ln[F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2))/F_\alpha(\rho_1, \rho_2)]} \quad (9)$$

and

$$\sigma^2 \geq \frac{\alpha(\alpha-1)\Delta\mu^2}{2\ln[F_\alpha(\Phi_2(\rho_2), \Phi_1(\rho_1))/F_\alpha(\rho_2, \rho_1)]}, \quad (10)$$

as above. With the above assumptions, the right-hand side in Eqs. (9) and (10) is genuinely negative. Thus, if $F_\alpha(\rho_1, \rho_2) < F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2))$, the probing protocol does not give us any relevant information. This observation suggests that in order to guarantee relevant information, one should maximize $F_\alpha(\rho_1, \rho_2)$ by choosing $\rho_1 = \rho_2 = \rho$, as there is very little control over $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2))$ in the case of unknown coupling U .

We note here that due to the similar role of σ and $\Delta\mu$ in Eq. (6), our probing protocol can be used to get bounds for unknown frequency shift $\Delta\mu$ if σ is known instead. In this case, the same measurement data could be used and lower bounds for $\Delta\mu$ would be determined as

$$\Delta\mu \geq \sqrt{\frac{2\sigma^2 \ln[F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2))/F_\alpha(\rho_1, \rho_2)]}{\alpha(\alpha-1)}}, \quad (11)$$

$$\Delta\mu \geq \sqrt{\frac{2\sigma^2 \ln[F_\alpha(\Phi_2(\rho_2), \Phi_1(\rho_1))/F_\alpha(\rho_2, \rho_1)]}{\alpha(\alpha-1)}}, \quad (12)$$

when $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2)) < F_\alpha(\rho_1, \rho_2)$ and $F_\alpha(\Phi_2(\rho_2), \Phi_1(\rho_1)) < F_\alpha(\rho_2, \rho_1)$, respectively. Similarly, if both $\Delta\mu$ and σ were unknown, we could get lower bounds for their ratio $\Delta\mu/\sigma$.

The above analysis was performed for the full generality of the α fidelities, but the same would also hold for the common fidelity of quantum states, obtained by choosing $\alpha = 1/2$. As suggested by the theoretical results in [18], freedom to choose α can lead to improved precision in probing protocols, so here we exploit the whole range $\alpha \in [1/2, 1)$ to get as tight bounds as possible.

Next, we implement the two frequency states with $\Delta\mu > 0$ and experimentally determine the values of $F_\alpha(\rho_1, \rho_2)$, $F_\alpha(\rho_2, \rho_1)$, $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2))$, and $F_\alpha(\Phi_2(\rho_2), \Phi_1(\rho_1))$ to get upper bounds for σ with our probing protocol.

IV. THE EXPERIMENT

In Fig. 4, we present the experimental setup. The photon source (PS) is a type-I beta-barium borate crystal, which is pumped with a tightly focused continuous-wave laser of the wavelength 405 nm. The crystal randomly produces a pair of photons through the spontaneous parametric down-conversion process in a wide spectrum around 810 nm. At PS, the *signal photons*' polarization is prepared to an initial probe state ρ by passing it through a polarizer rotated to a fixed angle with respect to the \leftrightarrow plane. Here, \updownarrow and \leftrightarrow correspond to vertical and horizontal polarizations, respectively. The *idler photon* in the upper branch is registered by the single-photon detector D_0 , which triggers the coincidence counting electronics (CC) to monitor the single-photon detector D_1 for data collection of the signal photon in the lower branch.

The signal photon first goes through the interference filter (IF). Tilting the IF changes its transmission bandwidth and, as a consequence, the central frequency μ of the Gaussian frequency distribution, while keeping its standard deviation σ as it was. This controlled transformation allows us to change the initial frequency state ξ into ξ_1 and ξ_2 , and thus choose $\Delta\mu$, which needs to be nonzero for our protocol to work.

FIG. 5. The experimentally determined upper bounds of the unknown parameter σ . Here, the coupling is a 5 mm quartz plate. The panel on the left-hand side illustrates the upper bounds of the unknown σ . We see that as α approaches 1, this measurement gives the tighter upper bound B_2 as $1.82 \times \sigma$, where the actual standard deviation is $\sigma = 5.68 \times 10^{11}$ Hz. The panel on the right-hand side presents the fractions $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2))/F_\alpha(\rho_1, \rho_2)$ and $F_\alpha(\Phi_2(\rho_2), \Phi_1(\rho_1))/F_\alpha(\rho_2, \rho_1)$, corresponding to the bounds in the left panel. We see that in both cases, the fraction is less than one for $\alpha \in [1/2, 1)$, and thus the use of the bounds $B_1(\alpha)$ and $B_2(\alpha)$ is justified.

The probing measurement is performed at the measurement stage. First the system (frequency) and the probe (polarization) are coupled as the signal photon goes through birefringent quartz plates (QP). This causes the channels Φ_1 and Φ_2 , which change the polarization states ρ_1 and ρ_2 , respectively.¹ After the QP, the signal photon passes through a combination of a half-wave plate (HWP), a quarter-wave plate (QWP), and a polarizing beam splitter (PBS). Rotating the QWP and the HWP changes the measurement basis of the PBS, and allows for full state tomography of the polarization states $\Phi_1(\rho_1)$ and $\Phi_2(\rho_2)$. For each measurement basis, we used 60 s integration time.

Measurement of how channels Φ_1 and Φ_2 change some initial probe states can give insight on how the optimal initial probe states should be chosen: In our case, polarization tomography after interaction with frequency shows that the diagonal terms in the $\{\leftrightarrow, \updownarrow\}$ basis remain constant and there is decay and rotation of the complex phase in the off-diagonal terms when the quartz plates in the experimental setup are fixed in the same orientation. This suggests a dephasing-type dynamics for the probe, for which optimal initial states were shown to be $\rho_1 = \rho_2 = |+\rangle\langle+|$, where $|+\rangle = \frac{1}{\sqrt{2}}(|\leftrightarrow\rangle + |\updownarrow\rangle)$ [18]. As a consequence, we choose to prepare our initial probe states close to

$$\rho_1 = \rho_2 = \rho := |+\rangle\langle+|. \quad (13)$$

The initial probe states in the experiment were determined to be

$$\rho_1 = \begin{pmatrix} 0.513 & 0.482 - 0.006i \\ 0.482 + 0.006i & 0.487 \end{pmatrix}, \quad (14)$$

$$\rho_2 = \begin{pmatrix} 0.535 & 0.496 - 0.017i \\ 0.496 + 0.017i & 0.465 \end{pmatrix}, \quad (15)$$

¹We emphasize that even though the dynamics induced by a QP coupling is well known once its optical axis is fixed, any assumption on the coupling or the channels is not used to derive our protocol and it would work similarly for any other coupling, as illustrated later by fixing randomly rotated orientations to each QP in combinations.

where we have used the matrix representation $|\leftrightarrow\rangle = (1, 0)^T$ and $|\updownarrow\rangle = (0, 1)^T$. We fixed the control parameter as $\Delta\mu = 7.95 \times 10^{11}$ Hz (in wavelength $\Delta\lambda = 1.73$ nm). We used multiple different thicknesses of quartz plates and their combinations, corresponding to different system-probe couplings U . As an example, in the case of a 5 mm quartz plate as the coupling, the corresponding evolved probe states were

$$\Phi_1(\rho_1) = \begin{pmatrix} 0.51 & 0.435 + 0.073i \\ 0.435 - 0.073i & 0.49 \end{pmatrix}, \quad (16)$$

$$\Phi_2(\rho_2) = \begin{pmatrix} 0.509 & 0.257 + 0.329i \\ 0.257 - 0.329i & 0.491 \end{pmatrix}. \quad (17)$$

In Fig. 5, we plot the upper bounds of Eqs. (7) and (8) for the unknown σ as a function of the parameter α . The upper bounds are given in units of the actual value of standard deviation $\sigma = 5.68 \times 10^{11}$ Hz (about 1.24 nm in wavelength). We note that the freedom to choose α leads to significantly tighter bounds: increasing α towards $\alpha = 1$ tightens the upper bound significantly, from $\tilde{\sigma} \leq 2.22\sigma$ to $\tilde{\sigma} \leq 1.82\sigma$. In this case, it is clear that the lack of input symmetry in F_α leads to two different bounds $B_1(\alpha)$ and $B_2(\alpha)$, and $B_2(\alpha)$ leads to a tighter upper bound.

The protocol was repeated for multiple other couplings, implemented with different thicknesses x of quartz plate combinations rotated in different orientations. The results are summarized in Fig. 6. Here, the thicknesses x are listed for completeness, but knowledge of the QP thickness—as any other properties of the coupling—is irrelevant for our protocol. For each coupling, the validity of the bounds was checked and the tightest bound was determined by comparing $B_1(\alpha)$ and $B_2(\alpha)$ for different values of α , as explained for the example case of 5 mm quartz plate in Fig. 5.

In Fig. 6, the blue crosses are the tightest upper bounds determined with the quartz plate combinations of different thickness x with the optical axes in the same direction. The solid blue line is the corresponding theoretical prediction, plotted by using the solution of polarization dynamics in [19]. We note that first the bounds become tighter as the thickness increases, but after 7 mm, the bounds become less and less tight. This tells us that from 2 to 7 mm, the evolved probe states

FIG. 6. The experimentally determined tightest upper bounds of the unknown parameter σ for different couplings U (color online). The x axis is the used quartz plate combination thickness, corresponding to different couplings and B_{inf} is the smallest value of the functions $B_1(\alpha)$ and $B_2(\alpha)$ for the optimal value of α , in units of the actual σ . The blue crosses correspond to measurements where all quartz plates are aligned in the same direction and the blue line is the corresponding theoretical prediction for the measured upper bound as a function of the QP thickness. The slanted red crosses correspond to measurements where the orientation of each quartz plate was fixed by rotating it in a randomly chosen angle. The slanted red cross at 7 mm corresponds to a combination of 2 and 5 mm quartz plates, the slanted red cross at 15 mm corresponds to a combination of 5 and 10 mm quartz plates, and the slanted red cross at 17 mm corresponds to a combination of 2, 5, and 10 mm quartz plates, all rotated in randomly picked and unknown angles. The error bars are due to the photon-counting statistics, and they are standard deviations of bound values calculated by the Monte Carlo method.

$\Phi_1(\rho_1)$ and $\Phi_2(\rho_2)$ become less and less similar to each other with respect to α fidelity, decreasing $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2))$ as the thickness x increases. After 7 mm, the bounds become less and less tight, which means that the evolved states $\Phi_1(\rho_1)$ and $\Phi_2(\rho_2)$ become more and more similar, increasing $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2))$. The measurement with coupling that corresponds to the 20 mm quartz plate combination is not shown in Fig. 6 because in that case, the evolved probe states became more similar than the initial states, and thus we got $F_\alpha(\rho_1, \rho_2) < F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2))$, which meant that the measurement data do not give any nontrivial bounds.

The slanted red crosses in Fig. 6 are the tightest upper bounds determined with the quartz plate combinations of different thickness x with the optical axes fixed in randomly chosen and unknown directions, corresponding to truly unknown couplings. For these cases, the orientation of quartz plates in the combinations is set by choosing a random and fixed direction independently for each of the quartz plates. Then, state tomography is performed for the evolved polarization states after interaction with the frequency in the QP combination. We note that in the case of $x = 7$ mm, the coupling with randomly fixed QP orientations leads to a slightly less tight bound than in the case of the fixed orientation. On the other hand, when $x = 15$ mm, the bounds given by the randomly oriented quartz plates give a significantly tighter bound than the same combination with all the plates set in the same orientation. This case is the tightest bound that we achieved in all of the measurements. Thus, with our protocol, modifications of the system-probe coupling can be used to tighten the obtained

bounds even if the effect of the modification in the resulting probe dynamics cannot be analyzed.

In [30], it was shown that the quantum Rényi divergences are continuous functions with respect to their argument states. As the α fidelities are continuous functions of the Rényi divergences, the α fidelities are also continuous, and thus small deviations in the tomography are not critical for the determined α -fidelity values. To experimentally test the sensitivity of our protocol with respect to the precision of probe tomography, we performed initial probe state tomography again by using only 10 s integration time for each basis. The smaller sample size changed the resulting states only slightly, and the average difference between the bounds obtained from 60 and 10 s tomography was 4.19% of the bound with 60 s tomography. This serves as experimental evidence for the robustness of our approach.

As illustrated by Eq. (7), Eq. (8), and our experimental data, this approach can give only analytically derived bounds for the unknown parameter to be determined and not its actual value. This is a trade-off of allowing the measurement protocol to function with no knowledge of the coupling U which the probing is based on.

V. CONCLUSIONS AND OUTLOOK

In this paper, we presented an experimental realization of a quantum probing protocol that works with unknown system-probe coupling. Our system of interest was the frequency of a photon and the unknown parameter of interest was the standard deviation of its Gaussian spectrum. The frequency spectrum was realized in two Gaussian distributions with different means and each of them was coupled to their corresponding polarization probes. Comparison of the evolved polarization states was applied in the generalized data-processing inequality, which gave us analytically derived upper bounds for the standard deviation as functions of the measured probe states.

We repeated the measurement for multiple system-probe couplings, implemented with quartz plate combinations of different thicknesses. To emphasize how our protocol does not rely on any knowledge of the coupling, we performed it by also using combinations of quartz plates whose orientations were fixed in randomly chosen and unknown angles. The experimentally determined standard-deviation upper bounds showed that there was no benefit of knowing the quartz plate orientations and, actually, the tightest upper bound for the unknown parameter was obtained with an unknown coupling. These experiments pave the way for different kinds of measurement protocols that do not rely on high-precision implementation and control of some desired coupling or knowledge of the coupling scheme at all. On a more foundational level, these results broaden the understanding of the limitations and possibilities of measurements more generally.

In this work, we have performed full tomography for both evolved probe systems. For qubit systems, tomography is fast in many cases, but for higher-dimensional systems, the number of parameters to be determined increases quadratically as a function of the dimension. As our probing protocol requires only the values of α fidelities, the natural question arises: is it necessary to perform full tomography for both probes?

If tomography of the first measured probe system shows that its density matrix has full rank, then full tomography of the other probe system is necessary. This is a consequence of a result in [31], which states that the fidelity $F_{1/2}(\sigma, \xi)$ between a known fixed reference state σ and an entirely unknown state ξ can be estimated without full tomography if and only if σ does not have full rank. This result is easily generalized to α fidelities. Thus, if tomography is done first for one of the evolved probes and its density matrix is not full rank, the α fidelity can be measured without full tomography of the second probe. The mathematical tools for constructing such measurements have been introduced in [31] and experimentally implemented to fidelity of two-photon polarization states in [32]. This demonstrates that estimating α fidelities for our probing purposes can be performed more efficiently, especially in the case of higher-dimensional polarization probes. Furthermore, if the first evolved probe state is determined to be pure, namely, $\Phi_1(\rho_1) = |\phi\rangle\langle\phi|$, then full tomography for the other evolved probe state is not necessary. In this case, we have $F_\alpha(\Phi_1(\rho_1), \Phi_2(\rho_2)) = [(\langle\phi|\Phi_2(\rho_2)|\phi\rangle)]^\alpha$, where $\langle\phi|\Phi_2(\rho_2)|\phi\rangle$ is the probability of outcome $|\phi\rangle\langle\phi|$ in the binary projective measurement $\{|\phi\rangle\langle\phi|, \mathbf{1} - |\phi\rangle\langle\phi|\}$.

Also, *a priori* information about the channels can be exploited: If some matrix elements are known to remain invariant in channel Φ_1 and/or Φ_2 , it suffices to measure only the matrix elements that change. In our case, the diagonal elements remain almost unchanged and thus the number of projective measurement bases could be reduced from 3 to 2, but for higher-dimensional probe systems, the improvement could be more significant.

In the polarization-frequency model, the transition from Markovian to non-Markovian polarization dynamics has been detected experimentally [19]. In that case, the relation of the heights of two Gaussian peaks in a double-peaked frequency spectrum controlled the transition when the widths and the distance of the Gaussians were fixed. With some modifications, our approach could be used to estimate the relative heights, and possibly to also deduce the Markovian or non-Markovian character of the dynamics. This would allow one to make accurate conclusions about the global properties of the polarization dynamics by performing measurements only at single unknown point in time.
